voltages would be in equilibrium among each other with respect to magnitude, phase, and curve shape, and both these voltages would be oppositely equal, as shown in Figure 19. The current would have a peaked shape, as also transferred from Figure 4 to Figure 19, and this current and these voltages would satisfy equation 5, derived in absence of a dissipating resistance. In order to sustain these conditions the external voltage must have a value equal to *Ri*, since the impressed voltage has no other work to do than compensating the ohmic drop in the circuit. With currents and voltages as expressed by equation 5, the first and the third terms on the left-hand side of the complete equation 27 neutralize each other. Hence, in this case the external voltage must be chosen as

$$e(\vartheta)=\rho A,\ \text{or}\ e_r(t)=Ri \tag{36}$$

which is graphically represented in Figure 20.

Thus, in nonlinear oscillatory circuits true resonance can be sustained if the impressed voltage has a magnitude, frequency, and curve shape as given by the ohmic drop of the current constituting a nonharmonic natural oscillation. The smaller the resistance, the lower is the voltage necessary to sustain the resonance state. The voltage to be impressed can be conceived of as an infinite Fourier series

$$e_r(t)=e_1(\nu_1 t)+e_3(\nu_3 t)+e_5(\nu_5 t)+\ldots \tag{37}$$

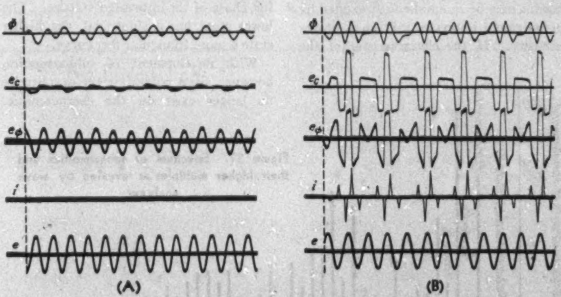
wherein the functions $e(\nu t)$ are sine or cosine functions and ν_1 is the natural frequency of the circuit.

If the circuit is fed, not by this peaked voltage but by a sinusoidal voltage of the fundamental frequency ν_1 and the amplitude E_1 as indicated in Figure 20, then a voltage, as shaded in this figure, remains as a deficiency. This voltage Δe is separately plotted to the negative side in order not to crowd the figure. In the present case this voltage contains all the higher harmonics of equation 37, of which obviously the third is preponderant. The residual voltage Δe will produce currents and inductive and capacitive voltages changing the original curve shapes of Figure 19 until equilibrium is established. Because of the curved characteristic of the circuit, no linear superposition will occur. However, it is obvious that the actual currents and voltages will be so distorted that they contain a different amount of the third and higher harmonics than before.

Let us now feed the circuit by a voltage not of natural frequency ν_1 but of three times this frequency, as represented in Figure 21. The impressed voltage $e_3(\nu_3 t)$ is the second best approximation to the peaked voltage e_r originally required and there remains as a deficiency the voltage Δe, shown shaded and plotted in Figure 21. This residuum contains a substantial wave of natural frequency ν_1, as plotted dashed by e_1, which now acts as an uncompensated and thus, as a distorting voltage in the circuit. This will produce currents and voltages which are essentially of the natural frequency which the circuit had before, as in Figure 19. Thus, we see that impressing a voltage $e_3(\nu_3 t)$ on the saturated circuit will create, in addition to currents i_3, also substantial currents $i_1(\nu_1 t)$ and correlated voltages e_{C1} and e_{L1}. All of these have 1/3 of the supply frequency and therefore, constitute a subharmonic phenomenon with respect to the source. Further currents of frequencies 5/3, 7/3, and so forth, the supply frequency, and of different amplitudes, will be produced by the higher harmonics contained in Δe of Figure 21.

By the actual currents now flowing in the system, the curve shapes will deviate considerably from those of Figure 19. The current i and the voltages e_L and e_C will change in magnitude and thereby the natural frequency also will be changed Thus the two voltages will come out of shape and out of phase and hereby will be enabled to take up completely between them the feeding voltage e_3.

If we feed the circuit by a voltage $e_5(\nu_5 t)$ as indicated in Figure 22, there now remains in Δe as a main deficiency a voltage e_1 of 1/5 and a voltage e_3 of 3/5 the feeding frequency. The further development of currents and distortions corresponds to that described before, and we see that subharmonics of 1/5 and 3/5 the frequency of the feeding voltage may appear, and also higher order oscillations of the mode 7/5 and more. The same argument can be applied if the circuit is fed by a voltage of any harmonic frequency contained in the original ohmic voltage of the natural oscillation, as expressed by equations 36 and 37.



Figures 26(A) and (B). Two states of unstable amplitudes as caused by subharmonics under the same circuit conditions as before, except the switching-on exerted at two intermediate phase angles

Thus, we conclude that an oscillatory circuit of nonlinear characteristic is able to respond in its fundamental natural oscillation to impressed voltages of a frequency of any and all of its natural higher harmonics. This refers to any possible natural oscillation of the circuit. However, we have seen that the natural frequency depends greatly on the intensity of the oscillation, as shown by Figures 5 and 6. Hence, we realize that such subharmonic resonance can occur only if the current and voltages produced are of such intensity that the exact ratios 1:3, 1:5, 3:5, and so forth, between the fundamental natural frequency and the impressed frequency are established. This will require for every given characteristic a certain magnitude of the impressed voltage, or magnitudes between certain limits. Otherwise, the 1/3rd, 1/5th, and lower subharmonics cannot be excited by the mechanism described.

The ohmic resistance of the circuit plays a decisive part. At $R=0$, all the voltages of equation 37 can excite the circuit up to the necessary amplitude and thus, all the subharmonics of any mode might be created. At low resistance, relatively small voltages of the modes e_3, e_5, and so forth, will be sufficient to produce subharmonics. With greater resistance, much higher voltages are necessary to balance the ohmic drop as in equation 36 at a resonant amplitude, and only the highest mode, usually 1/3, may remain active. A further increase of the circuit resistance may be used to suppress entirely any accidental subharmonic resonance.

Depending on the resistance, a range of magnitudes in the impressed voltage is able to excite subharmonics and the various ranges of e_3, e_5, and so forth, even may overlap. Therefore, a number of subharmonic currents of different modes as 1/3, 1/5, and so forth, and their higher harmonics, may be simultaneously excited by an individual impressed voltage of proper intensity. If the characteristic of the circuit is not symmetrical in its plus and minus behavior, not only the odd but also the even subharmonics of modes 1/2, 1/4, and so forth, and their higher harmonics will be produced. It also can happen that a symmetrical characteristic is unsymmetrically traversed by the oscillations and that even modes of sub- or superharmonics will be self-excited in this way.

The creation of subharmonics in circuits of nonlinear characteristic has been actually observed down to a mode of 1/9 of the impressed frequency. Figure 23 shows an oscillogram versus time in which a repetition and near repetition of the fundamental phenomena can be recognized after every 6th and every 3rd cycle of the impressed voltage. Here the predominant oscillation of the flux is of the mode 5/3. The duration of the switching-on transients in this test which was taken with very high voltage, is conspicuously short. If the magnetic characteristic Φ versus i, or B versus A, is directly measured, for example on the screen of a cathode-ray oscillograph, an identical curve will be traced only after complete repetition. The intermediate traces can be made visible by a slight artificial displacement of the individual curves. Figure 24 shows such a cathode-ray oscillogram on which five traces can be distinguished, indicating that subharmonics of at least the 1/5th mode have been present.

The existence of two possible stable points of voltage and current on the magnetic characteristic is well established, one of low, another of higher current. This can be derived by sole consideration of the amplitudes of oscillations. The oscillograms of Figures 25(A) and (B) give an over-all picture of the transient and the steady state performances in these two states. The selection among the two states depends entirely on the switching phase of the impressed voltage. The lower state has a sinusoidal, the higher state a more triangular flux curve.

With development of subharmonics, however, fixed points for the amplitudes no longer exist on the characteristic. Rather, these amplitudes wander up and down in the rhythm of the subharmonic oscillations and thus, the equilibrium will be greatly distorted. Figure 26(A) and (B) give oscillographic pictures of two additional states of the system which develop under exactly the same conditions as in Figure 25(A) and (B) except for the phase angle of switching. Figure 26(A) contains a subharmonic of mode 1/3 of medium amplitude, as is clearly visible in the flux curve. Higher harmonics also develop, as seen from the capacitive voltage e_C. Measurements by a wave analyzer yield their frequencies as 5/3, 7/3, 9/3, 11/3, and 15/3. Of these, the 9/3 and 15/3 modes also could be conceived of as the 3rd and 5th harmonics of the supply frequency.

Very different is the appearance of Figure 26(B). Here, a weak subharmonic of mode 1/4 and a strong one of mode 1/2 are present, and in addition a very strong harmonic mode 3/2 followed by many odd and even multiples of the mode 1/4, as disclosed by the wave analyzer, the entire spectrum of which is shown in Figure 27. It is a remarkable way in which the curve shapes are hereby distorted, for example those of the current or the capacitive voltage. The predominant wave of the flux seems to be that of the mode 3/2, in accord with Figure 27, while in the capacitive voltage the mode 1/2 is intensely visible, distorting completely the symmetry in width and amplitude of every two subsequent oscillations.

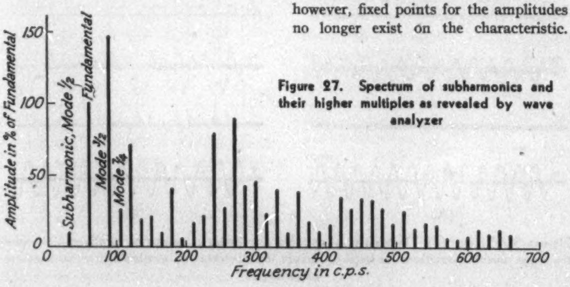


Figure 27. Spectrum of subharmonics and their higher multiples as revealed by wave analyzer

Summary

It is shown that the distorted curve shapes of natural oscillations can be rigorously derived from the saturation characteristic of the oscillatory circuit by means of simple integrations. The natural frequency is not constant as under linear conditions, but varies greatly with the amount of saturation.

For forced oscillations, a concise differential equation is given covering all possible cases by only four parameters. The solution can be evaluated for any initial conditions by a straight-forward step-by-step construction. It shows graphically strange curve shapes of flux, current, and voltages, of no regularity with respect to periodic repetition or symmetrical behavior during the transient state.

In the steady state, a rigorous linearization of the differential equation allows considering the effect of saturation quantitatively as a distortion of the impressed voltage. The final effect on magnitude and curve shape can be evaluated by repeated superposition of the residual distorting voltage. Intense higher harmonics are produced in this way.

Consideration of the resistance voltage as actually present in the state of free oscillations shows that natural oscillations can be sustained in true resonance by an impressed voltage of definite magnitude and curve shape, requiring in series circuits a highly peaked voltage curve. Hence, the saturated circuit can respond to any constituent harmonic of this shape, leading to the forced development of subharmonics to the frequency of the supply voltage within certain ranges of its magnitude. If the ohmic resistance is small a multitude of such subharmonics and all their higher harmonics may develop.

The theoretical results are illustrated by oscillograms taken on actual circuits of high saturation. These experiments confirm that, depending on the switching angle, many distinct oscillatory states of the circuit exist under the same over-all conditions, producing widely different currents and voltages. Within one subharmonic period of forced oscillation different parts of the characteristic may be subsequently traversed, creating odd and even sub- and super-harmonics even under externally symmetrical conditions.

No Discussion

Comparative Performance Records—Steel and Wood Transmission Lines

C. A. BOOKER
NONMEMBER AIEE

THE PREPARATION of this paper has been suggested to stimulate thought and discussion on the question of wood versus metal transmission-line supports. It will present statistical performance records of several different types of steel- and wood-supported transmission lines.

The body of the paper should be prefaced with the statement that the comments and conclusions herein apply to New England territory which has an average of about 30 thunderstorm days per year, and may or may not be applicable in whole or in part in other regions. It also should be noted that the normal direction of storms is parallel with our main transmission lines, so that the exposure to each storm is prolonged sometimes for several hours.

Useful Life and Obsolescence

The data will show that most of our high-voltage lines, in keeping with the trend of thought at the time they were built, have employed steel supporting structures until quite recently. The principal reason for this was the relatively short life expectancy of wood structures. Various preservative treatments for field application have greatly increased this expectancy, and they, together with the development of full-length pressure-treated timber products, have done much to alleviate this major objection to the use of timber.

At the present time the useful life of treated timber corresponds roughly with the cycle of obsolescence. In the opinion of many engineers, a life of 30 or 40 years is one of the principal recommendations for wood construction, as it offers reasonably frequent opportunities to consider extensive modernization without the dead weight of a large unamortized capital investment.

Trend to Wood Structures

About 15 years ago, after an analysis of the operating histories of our various high-voltage lines, it was concluded that a properly designed wood line should give superior service from an interruption standpoint. It was felt that such a design would incorporate single-circuit construction, horizontal configuration, considerable wood insulation with no reduction in porcelain, an aerial direct stroke wire, reasonably short span lengths, low wire stresses, natural round rather than sawn or machine-shaved timbers, simple hardware, and a minimum number of wire guys.

pared, each with a brief summary of cumulative operating results covering the period from 1921 to 1947 inclusive. Brief historical comments will be required only to supplement and point up these data. Figures 1 to 9 inclusive, and Figure 10, show lightning outages for various types of line, the approximate construction dates of which are noted on the various figures.

Table I shows the cumulative record of structural failures under extraordinary external loading conditions.

The lightning outage experience record is presented on three different bases.

1. Interruptions per 100 circuit-mile years. This is based on the total number of circuit operations.

2. Interruptions per 100 structure-mile years. This eliminates the effect of simultaneous operations on 2-circuit tower lines and gives a figure comparable to the same structures carrying but one circuit. It also permits a determination of the per cent of double-circuit faults, which will be discussed later.

3. Interruptions per 100 right-of-way-mile years. These figures are included on the theory that a more or less definite number of lightning disturbances occur within limited areas such as a transmission line right of way, and that the strokes within such areas will be divided between the various available targets (or lines). That is, two parallel lines should together suffer a negligible increase in interruptions over a single circuit of the same design on the same right of way. This theory follows from the absence of simultaneous double-circuit operations on the large mileage of twin-circuit lines covered by this paper.

Lightning Disturbances—Early Double-Circuit Steel Lines

Figure 1 illustrates a double-circuit type of steel structure used rather extensively before suspension pin and cap insulators were satisfactorily developed. This line suffers 28.4 lightning disturbances per 100 structure-mile years. However, this number of disturbances results in a total of 44.6 switch operations, which indicates that 16.2 or 57 per cent must produce simultaneous faults in both circuits.

Figure 2 illustrates the type of structure which, with the advent of the disk insulator, supplanted that shown in Figure 1. Although from 5 to 7 disks in series were installed on such lines, no improvement in lightning outages occurred, possibly because the average height of wire and structure are greatly increased and consequently may be the target for a larger proportion of direct strokes. Sixty-three per cent of the lightning strokes result in double-circuit outages.

The severe sleet storms of November, 1921 and March, 1924 demonstrated that a vertical configuration of wires was a fertile cause of trouble under such conditions. It thereupon was determined to build all important future lines with a horizontal arrangement. Figure 3 is such a line, used on two important developments where the maximum service security was warranted. Here the wires are at an intermediate height between Figures 1 and 2. The difference in the record of the two lines reflects the use of different porcelain and arc-over devices. One of these lines suffers 76 per cent double faults and the other 57 per cent.

Lightning Disturbances—Wood Lines, No Aerial Ground

Figure 4 is a type of grounded-crossarm wood structure used extensively during and following World War I when steel was difficult to obtain. These lines usually are insulated with four disks. Each steel crossarm is grounded with a coil of wire at the pole butt. The apparent absence of adverse effect from the omission of an aerial ground wire, may be accounted for by better-than-average grounding conditions.

During the early 20's, less important lines were built using the grounded-crossarm H-frame structure illustrated in Figure 5. These lines have impulse insulation of the same order as Figure 3, but no aerial ground wire was installed so that the remarks in the caption of Figure 4 with respect thereto are also in order here.

Lightning Disturbances—Single-Circuit Steel Lines

In 1926 it became desirable to build a single-circuit line equivalent to Figure 3 but for about 50 per cent of the investment, as a second circuit would not be re-

quired for several years. Our studies resulted in a semiflexible steel structure of the type illustrated in Figure 6. The operating record of this type with eight and nine disks shows improvement over Figures 3 and 5, possibly because of the better shielding provided by the two aerial wires used in part to obtain longitudinal stability.

Later, the erection of a second circuit on the same right of way confirmed our hope that such independent circuits offered a practicable way to eliminate double-circuit interruptions. On our double-circuit towers as a whole, the foregoing figures show that about 60 per cent of the lightning strokes result in double-circuit outages. On parallel single-circuit lines, similar to Figure 6 or those to be hereinafter discussed, there have been no double-circuit interruptions during the time covered by this paper, a period encompassing 3,300 circuit-mile years of experience.

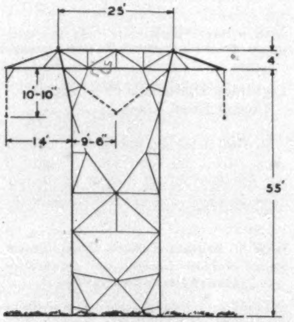

Figure 7*

Figure 7 illustrates the principal features of our 220-kv transmission lines, which closely follow the design developed in Figure 6. Detailed information on this line has been published recently by Ohio Brass Company.[1]

Lightning Disturbances—Wood Lines with Aerial Ground

The opening remarks mention our present preference towards the use of timber structures. Figures 8 and 9 show these structures for 66 and 110 kv respectively. The 66-kv line introduces about 15 to 18 feet of wood insulation, which, for impulse frequencies, is equivalent to 15 to 24 disks, depending on wave shape as modified by reflections from adjacent grounds. The 110-kv structure provides about 25 to 27 feet of wood, equivalent to 25 to 35 disks on the preceding basis. No lightning interruption has occurred on a 110-kv line of this type. There now are six examples of this type, having a total length of 95 miles and an experience record of 267 circuit-mile years (including 1948, not shown in the tabulation).

†This figure determined from that portion of this general type of construction on which completely segregated information is available.

Notes on Grounding Conditions

In the territory covered by this paper, the ground resistance at individual structures runs from 5 to over 1,500 ohms, with an average of about 390 ohms. Table II shows the range as determined from nearly 1,400 tests on about 150 miles of line.

Longitudinal counterpoise wires are being installed on some of the more important tower lines, and preliminary reports indicate very beneficial results.

Structural Failures

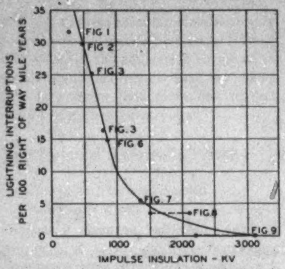

Figure 10. Curve showing relation of impulse insulation to lightning disturbances on lines with ground-wires

storms, when extensive damage occurred not only to utility plant, but to all types of structures. This table demonstrates the reliability of wood when properly used and maintained on transmission-line rights of way adequately cleared of trees. The ultimate replacement of wood structures or components may offer some problems if service interruptions are hard to schedule when the time arrives. These problems should not be difficult on our system as all important loads have alternate feeds.

Forest, brush, and grass fires frequently are mentioned as a possible objection to wood structures in timbered country. We have had many such fires cross our rights of way, and untreated poles are some times consumed where tall grass has grown around them. Creosoted poles in the same area and conditions have been charred, but none has ever been irreparably damaged.

Miscellaneous Remarks on Design

On future 110-kv extensions, we are contemplating the elimination of all guy wires by the use of brace poles or cross bracing. Also, it is worth noting in passing that in no case have any so-called Polarm structures been shattered by lightning after the aerial ground was in place. In some instances during construction, the top of the tall pole has been shattered when the pole ground only ran part way up the pole, before the longitudinal ground wire was run in and connected to the pole ground by the flying jumper which preserves the wood insulation.

Unfortunately, we have no comparative data to offer on the more conventional H-frame with two ground wires carried well above the crossarm. Such lines have not been used on our system because of our policy of avoiding any close approach to a vertical configuration, and our desire to obtain more of the benefits of wood insulation than practical H-frame dimensions allow. It would be necessary to use about a 50-foot crossarm to secure the same electrical characteristics in an H-frame that we have in a Polarm. When the extra protection of complete ground-wire shielding is desired, we use a separate ground-wire line with nothing else on it. This is considered only on single-circuit lines of the greatest importance.

Interruptions Related to Impulse Insulation

From the foregoing experience record, a curve has been prepared to reflect interruptions on a 100-mile right-of-way-year basis for lines having different impulse insulation levels and at least one aerial ground wire. This curve is shown in Figure 10 and convincingly shows the value of high impulse insulation and the relative ease of securing such insulation with wood structures.

Conclusion

A study of the various figures indicates that near immunity to lightning is obtained in this territory when a line incorporates in its design 2,500 to 3,000 kv of impulse insulation, corresponding clearances, and one or more ground wires. Lines operating at voltages up to at least 110 kv can be designed to meet these requirements without excess cost by taking advantage of the impulse insulating properties of wood.

Discussion

Earle Wild (Commonwealth Edison Company, Chicago, Ill.): Would Mr. Booker please give the correlation between the tower footing resistance and the excellent performance of the newer lines.

Is it not possible that these newer lines are the ones with the lower resistance so that they would logically have a better performance record than some of the earlier lines?

Also, how does the performance of your lines compare with the calculated theoretical performance as given by A. C. Monteith and others?

C. A. Booker: In reply to Mr. Wild's question, structure ground resistances on new lines average about the same as old. No special efforts to improve such conditions have been made except on some of the old tower lines where a longitudinal counterpoise wire is now being installed. Preliminary reports indicate considerable benefit from this installation.

Mr. H. R. Stewart, Electrical Engineer for our organization, stated that the line performance has been checked against the probability curves of A. C. Monteith[1] and also the later ones of E. L. Harder and J. M. Clayton.[2] The actual operating records are considerably less severe than the curve predictions. Possible explanations are that the tower footing resistance under lightning discharge conditions may be materially less than the values measured by the conventional reversed—d.c. "megger" method, or the number or severity of strokes per stormday in New England might be less than for the lightning data on which the published probability curves are based.

Stationary Networks and Transmission Lines Along Uniformly Rotating Reference Frames

GABRIEL KRON
MEMBER AIEE

Synopsis: This paper represents the first of a series of studies on the physical and mathematical analysis of the steady-state stability of conventional and long-distance transmission systems as influenced by the presence of voltage regulators and other control devices. As a first step attention is restricted to the transmission line as a component part of the over-all system and practical equivalent circuits are established for its representation, when the connected synchronous machines oscillate. For that purpose the basic equations of stationary networks are set up when viewed from uniformly rotating reference frames. An isolated inductor and capacitor, then a transformer, and finally a transmission line are used as examples. Their equations viewed from a simultaneously rotating and oscillating reference frame are given in reference 1.

THE CONCEPT OF "TRANSFORMATION OF REFERENCE FRAMES"

WHEN a stationary network is connected to a rotating machine, it usually is a simple matter to correlate their equations, since the latter are in most cases established along stationary axes for both machine and network. Difficulties arise, however, when the equations of the rotating machine happen to be established along rotating reference frames while the equations of the stationary network still retain their conventional form which is valid, of course, only for stationary reference frames. Such a case occurs, for instance, in transmission systems where synchronous generators are connected to a stationary transmission line.

In steady-state problems or in elementary small oscillation problems when the transmission line may be replaced by a tie-line (a single inductor) or when the synchronous machine may be considered balanced (no saliency, and so forth) the presence of a stationary network does not complicate the intended analysis. On the other hand, when in a hunting problem it is necessary to consider at the same time the shunt-capacitors of the transmission line and the saliency of the synchronous machine, lack of familiarity with the concept of "reference frames" and "transformation of reference frames" may lead to unnecessary complications.

THE METHOD OF REASONING OF CRARY AND CONCORDIA

In Park's method of analyzing synchronous machines the reference axes of both armature and field are rigidly connected to the field and rotate and oscillate (accelerate) with it. Hence no stationary network may be connected to the armature without further extension of the theory.

Crary[2] and Concordia[3,4] extended Park's equation to include any symmetrical stationary network connected to the armature. Their method of attack is as follows:

1. First they assume the synchronous machine axes not along the rotating (or accelerating) d, q, o axes, but along the stationary armature axes a, b, c, as Park originally did. In that case the synchronous machine equations are of the usual simplified form

$$e = Ri + p\psi = Ri + p(Li)$$

2. To this form they add the conventional equations of stationary networks connected to the a, b, c axes.

3. Afterward they transform both the machine and the network equations simultaneously from the a, b, c to the d, q, o axes in exactly the same manner as Park did for the machine alone.

The resulting equations are rather complicated. Also, it is difficult to add additional synchronous machines, say in the middle of the transmission line.

THE TENSORIAL METHOD OF ATTACK

Familiarity with the idea of transformation of reference frames would have suggested the following simpler method of attack for adding stationary networks to the armature of a synchronous machine:

1. First remove the stationary network from the synchronous machine.

2. Transform the machine and the network equations separately from the a, b, c to the d, q, o axes.

Since the transformed machine equations are already known, there was no need to establish them all over again. Hence it would have been sufficient to study the equations of only a stationary network along the accelerated axes d, q, o, or along any other arbitrary reference frame, along which a rotating machine itself was to be analyzed.

3. The resultant equations of the machine and of the network—both now being expressed along the same reference frame—are combined.

In fact, if the equivalent circuits of the machine and of the network are developed separately, it is sufficient to interconnect the networks themselves, without bothering to combine their equations first.

The foregoing reasoning is followed in this paper with the difference that the armature reference frame is assumed to rotate uniformly without any acceleration (small oscillation) in order to simplify the final equations. As a consequence it also will be necessary to study the small oscillations of synchronous machines along a uniformly rotating reference frame (Park

Manuscript submitted January 26, 1949; made available for printing May 2, 1949.

GABRIEL KRON is a Consulting Engineer with the General Electric Company, Schenectady, N. Y.

and his followers assume a simultaneously rotating and oscillating reference frame). The study of the equivalent circuit of an oscillating synchronous machine along this new frame will form the subject matter of a consequent paper.

The Physical Reference Frame

Equation of Voltage Along Stationary Axes

It will be assumed that the three axes a, b, c of the armature at 120 degrees from each other are replaced by two axes α, β at 90 degrees apart, Figure 1. The zero-sequence o axis will exist, but will be left out of consideration.

Let two sets of stationary networks, each with any number of meshes, be given, that are to be connected to the armature axes α, β of a synchronous machine, (or to the slip rings on the rotor of an induction motor). The system must be a symmetrical R, L, C network (it may include rotating machines with symmetrical structure); that is if symmetrical components are introduced the positive-sequence network must be the same as the negative-sequence network, while the zero-sequence network may be anything. The impressed voltage need not be symmetrical. (If the network is not symmetrical, time harmonics have to be introduced.)

The equation of voltage of the network is

$$e=L\frac{d^2q}{dt^2}+R\frac{dq}{dt}+Sq$$

where the component impedance tensors L, R, and S are not functions of θ or of time.

Since it is not known how the charges are transformed when reference axes are changed, it is necessary to replaced the charges by another set of variables, $i=dq/dt$ as it is known how the i's are transformed with a change of axes. (In the language of dynamics a "nonholonomic" reference frame must be introduced.) In terms of current variables the equation of voltage of any stationary network along stationary reference frames is

$$\boxed{e=Ri+Lpi+S\frac{1}{p}i} \tag{1}$$

or

$$e=Zi \tag{2}$$

where

$$Z=R+Lp+S\frac{1}{p} \tag{3}$$

If sinusoidal currents flow in the network and if their frequency with respect to the stationary conductors is n, then p becomes $jn\omega$

$$\omega L=X_L \quad \Big| \quad S/\omega=X_c$$

and the impedance tensor becomes

$$Z=R+jX_Ln-jX_cn^{-1} \tag{4}$$

Here $\omega=2\pi k$ where k is some base frequency in terms of which X_L and X_c are calculated. The actual frequency n is expressed as a fraction of the base frequency k.

Introduction of Rotating Axes

Let now the stationary axes α, β of each set of two meshes be replaced, Figure 1, by the two rotating axes d, q (or the rotating axes α, β of the induction motor rotor by the stationary axes d, q). That is let the currents i be replaced by i' with the aid of the equation

$$i=Ci' \tag{5}$$

where C is a function of θ. If all axes rotate with the same instantaneous velocity $p\theta$, the transformation tensor C for a single-mesh 2-phase case is

$$C=\begin{array}{c|c|c|}
 & d & q \\
\hline
\alpha & \cos\theta & -\sin\theta \\
\hline
\beta & \sin\theta & \cos\theta \\
\hline
\end{array} \tag{6}$$

(For an induction motor θ has opposite sign.) Substituting, the equation of voltage (1) becomes

$$e=R(Ci')+Lp(Ci')+S\frac{1}{p}(Ci')$$

Multiplying by C_t

$$C_te=(C_tRC)i'+C_tLpCi'+C_tS\frac{1}{p}Ci'$$

If along the rotating reference frames the various impedance tensors are defined by their laws of transformation as

$$\begin{array}{l|l}
R'=C_tRC & S'=C_tSC \\
L'=C_tLC & e'=C_te
\end{array} \tag{7}$$

the new equation of voltage viewed from an arbitrarily rotating reference frame becomes

$$e'=R'i'+L'(C^{-1}pC)i'+S'\left(C^{-1}\frac{1}{p}C\right)i' \tag{8}$$

where p and $1/p$ refer to all expressions to the right of them.

The "Christoffel Symbols" V and Γ

Let for the time being the capacitor be absent and $S'=0$. Considering the inductor term only

$$\begin{aligned}pCi'&=(pC)i'+Cpi'\\&=\frac{\partial C}{\partial\theta}p\theta i'+Cpi'\end{aligned}$$

Substituting

$$e'=R'i'+L'pi'+L'C^{-1}\frac{\partial C}{\partial\theta}p\theta i' \tag{9}$$

The expression

$$\Gamma=C^{-1}\frac{\partial C}{\partial\theta}=\begin{array}{c|c|c|}
 & d & q \\
\hline
d & & -1 \\
\hline
q & 1 & \\
\hline
\end{array} \tag{10}$$

is analogous to the rotation tensor γ_t' used in rotating machine studies, it has the same components but a different definition, since

$$\gamma_t'=C_t\frac{\partial C_t^{-1}}{\partial\theta}=\gamma_{m}^{\cdot n}$$

Γ is the contravariant form of the "Christoffel symbol" V' (or rather of the "nonholonomic Christoffel symbol")

$$V'=L'\Gamma'=(C_tLC)C^{-1}\frac{\partial C}{\partial\theta}=C_tL\frac{\partial C}{\partial\theta} \tag{11}$$

Using index notation, V and Γ are special cases of several geometric objects, namely

$$V'=V_{mk}=\Gamma_{ks,m}=[ks,m]=-\Omega_{ks,m} \tag{12}$$

$$\Gamma'=L^{-1}V=V^{m}_{\cdot k}=\Gamma_{ks}^{m}=\begin{Bmatrix}m\\ks\end{Bmatrix}=-\Omega_{ks}^{m} \tag{13}$$

None of these concepts are tensors; all are geometric objects (see reference 5).

In direct notation two different symbols V and Γ must be used to represent the covariant and contravariant forms of the

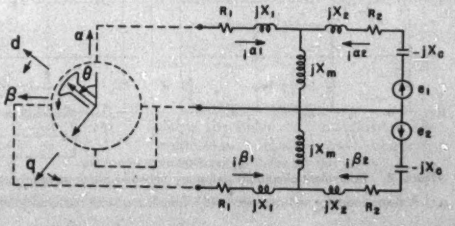

Figure 1. Stationary network, to be connected to a synchronous machine

same geometric object, though it is a very confusing practice. Hence occasionally the index notation also is used here to keep the physical concepts straight.

THE EQUATION OF VOLTAGE WITH NO CAPACITORS

In terms of Γ equation 9 becomes

$$\mathbf{e}'=\mathbf{R}'\mathbf{i}'+\mathbf{L}'\frac{d\mathbf{i}'}{dt}+\mathbf{L}'\boldsymbol{\Gamma}'\mathbf{i}'p\theta \tag{14}$$

and in terms of $\mathbf{V}$ it becomes

$$\mathbf{e}'=\mathbf{R}'\mathbf{i}'+\mathbf{L}'\frac{d\mathbf{i}'}{dt}+\mathbf{V}'\mathbf{i}'p\theta \tag{15}$$

$$e_m=R_{mn}i^n+L_{mn}\frac{di^n}{dt}+[ks,m]i^k\frac{dx^s}{dt}$$

It may be seen that when a stationary 2-phase inductor is viewed from a rotating frame, an apparent generated voltage appears as if the stationary inductor were a rotating machine. However, it is interesting and important to note that no torque is exerted on the stationary coil by the rotating axes since

$$\text{torque}=\mathbf{i}'^{*}\mathbf{G}'\mathbf{i}'$$

and the torsion tensor $\mathbf{G}'$ has no existence in the present dynamical problem (its place is being taken by $\mathbf{V}'$, a nontensor object).

THE "ABSOLUTE" TIME DERIVATIVE $\mathbf{p}$

For the purpose of the present paper still another form of the voltage equation will be employed. If $\mathbf{L}'$ in equation 14 is factored out, the equation assumes the form

$$\mathbf{e}'=\mathbf{R}'\mathbf{i}'+\mathbf{L}'(\mathbf{I}p+\boldsymbol{\Gamma}'p\theta)\mathbf{i}' \tag{16}$$

where $\mathbf{I}$ is the unit tensor. The expression in parenthesis is a tensor of valence two and will be denoted by $\mathbf{p}'$. It is a generalization of $p=d/dt$ and is called the "absolute" (or "covariant") time derivative δ/dt in tensor analysis

$$\mathbf{p}'=\frac{\delta}{dt}=\mathbf{I}p+\boldsymbol{\Gamma}p\theta=p_{\cdot n'}^{m'} \tag{17}$$

The voltage equation 16 in terms of $\mathbf{p}$ becomes

$$\mathbf{e}=\mathbf{R}'\mathbf{i}'+\mathbf{L}'\mathbf{p}'\mathbf{i}'=\mathbf{R}'\mathbf{i}'+\mathbf{L}'\frac{\delta\mathbf{i}'}{dt} \tag{18}$$

the same as that of a stationary impedance viewed from a stationary frame.

Comparing equation 18 with equation 8 it may be seen that the law of transformation of $\mathbf{p}'$ is

$$\mathbf{p}'=\mathbf{C}^{-1}\mathbf{p}\mathbf{C}\quad\Big|\quad p_{\cdot n'}^{m'}=p_{n\cdot}^{m}C_m^{m'}C_{n'}^{n} \tag{18A}$$

where along the stationary axes $\mathbf{p}=p\mathbf{I}=pI_{n\cdot}^{m}$. That is $\mathbf{p}$ is a once covariant and once contravariant tensor like $\gamma_t=\gamma_{\cdot n}^{m}$ and $\mathbf{C}=C_n^m$ are.

THE EQUATION OF VOLTAGE WITH CAPACITORS

Returning to the general equation of voltage, equation 8, with $\mathbf{S}$ different from zero, let it be written as

$$\mathbf{E}'=\mathbf{S}'\left(\mathbf{C}^{-1}\frac{1}{p}\mathbf{C}\right)\mathbf{i}'$$

where

$$\mathbf{E}'=\mathbf{e}'-\mathbf{R}'\mathbf{i}'-\mathbf{L}'\mathbf{p}'\mathbf{i}' \tag{19}$$

In order to get rid of the inverse p let first both sides be multiplied by $\mathbf{C}\mathbf{S}'^{-1}$

$$\mathbf{C}\mathbf{S}'^{-1}\mathbf{E}'=\frac{1}{p}\mathbf{C}\mathbf{i}'$$

and then by p

$$\mathbf{C}\mathbf{S}'^{-1}p\mathbf{E}'+(p\mathbf{C})\mathbf{S}'^{-1}\mathbf{E}'=\mathbf{C}\mathbf{i}'$$

($\mathbf{S}'^{-1}$ is not a function of θ or p.) Multiplying both sides by $\mathbf{C}^{-1}$

$$(\mathbf{I}p+\mathbf{C}^{-1}p\mathbf{C})\mathbf{S}'^{-1}\mathbf{E}'=\mathbf{i}'$$

The expression in parenthesis is $\mathbf{p}'$ and the equation may be written as

$$\mathbf{p}'\mathbf{S}'^{-1}\mathbf{E}'=\mathbf{i}'$$

Multiplying first by $\mathbf{p}^{-1}$, then by S'

$$\mathbf{E}'=\mathbf{S}'\mathbf{p}'^{-1}\mathbf{i}'$$

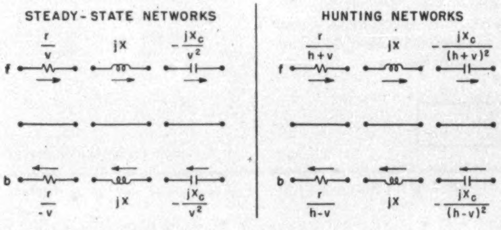
Substituting the value of $\mathbf{E}'$ the equation of voltage of a stationary network containing inductors $\mathbf{L}$ and capacitors $\mathbf{S}$, as viewed from arbitrarily accelerated reference frames, is

$$\boxed{\mathbf{e}'=\mathbf{R}'\mathbf{i}'+\mathbf{L}'\mathbf{p}'\mathbf{i}'+\mathbf{S}'\mathbf{p}'^{-1}\mathbf{i}} \tag{20}$$

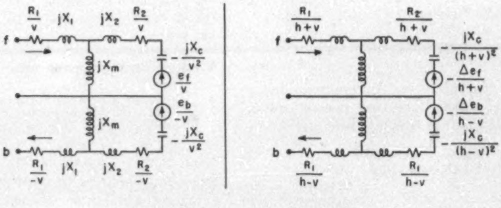
This equation has the same form as equation 1

$$\mathbf{e}=\mathbf{R}\mathbf{i}+\mathbf{L}p\mathbf{i}+\mathbf{S}p^{-1}\mathbf{i}$$

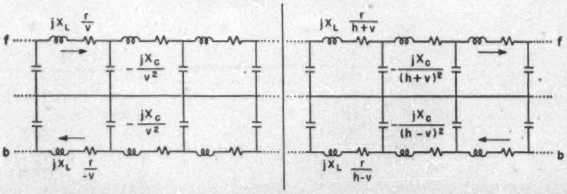
representing their equation viewed from *stationary* reference frames, with the dif-



a) RESISTOR, INDUCTOR AND CAPACITOR



b) TRANSFORMER WITH CAPACITOR LOAD



c) TRANSMISSION LINE

Figure 2. Equivalent circuits of stationary networks along uniformly rotating reference frame

(a) Resistor, inductor and capacitor (b) Transformer with capacitor load (c) Transmission line ference that all ordinary time derivatives $p = d/dt$ are replaced by "absolute" time derivatives $\mathbf{p} = \delta/dt$.

These last two equations are further illustrations of the "Generalization Postulates" (reference 5, page 115) whose purpose is to reduce the formulation of otherwise complex problems to the simplicity of common everyday usages. Equation 20 also may be written as.

$$\mathbf{e}'=\mathbf{Z}'\mathbf{i}' \tag{21}$$

where

$$\mathbf{Z}'=\mathbf{R}'+\mathbf{L}'\mathbf{p}'+\mathbf{S}'\mathbf{p}'^{-1} \tag{22}$$

Both equations are generalizations of equations 2 and 3 from stationary to uniformly rotating reference frames.

The definition of the "absolute" time derivatives $\mathbf{p}$ was already given in equation 17. It is still necessary to define its inverse, $\mathbf{p}^{-1}$.

CALCULATION OF $\mathbf{p}^{-1}$ WHEN $p\theta$ = CONSTANT

Later on it will be necessary to replace the general tensor equations by two sets of tensor equations, each relating to only one phase of a 2-phase system. For the present it will be sufficient to express only Γ and $\mathbf{p}$ along each of the phases in terms of compound tensors (namely in terms of tensors in which each component is a tensor) as

$$\Gamma=\begin{array}{c|cc} & d & q \\ \hline d & & -I \\ q & I & \end{array} \tag{23}$$

$$\mathbf{p}=\begin{array}{c|cc} & d & q \\ \hline d & pI & -p\theta I \\ q & p\theta I & pI \end{array}=\begin{array}{|cc|} \hline z_1 & z_2 \\ z_3 & z_4 \\ \hline \end{array} \tag{24}$$

where I is a unit tensor having as many diagonal components as the network has meshes (along one phase).

If, and only if, $p\theta$ is constant, then the inverse of $\mathbf{p}$ can be expressed as (reference 6, equation 10.43).

$$\mathbf{p}^{-1}=\begin{array}{c|cc} & d & q \\ \hline d & y' & -y'z_2y \\ q & -yz_3y' & y+yz_3y'z_2y \end{array}$$

$$y=z_4^{-1}=\frac{1}{p}I$$

$$y'=(z_1-z_2yz_3)^{-1}=\frac{p}{p^2+(p\theta)^2}I$$

Substituting, the 2-phase form of $\mathbf{p}'^{-1}$ is

$$\mathbf{p}'^{-1}=\frac{1}{p^2+p\theta^2}\begin{array}{c|cc} & d & q \\ \hline d & pI & p\theta I \\ q & -p\theta I & pI \end{array} \tag{25}$$

Comparing with equation 24 $\mathbf{p}'^{-1}$ can be expressed in the general (single-equation) form as

$$\boxed{\mathbf{p}'^{-1}=\frac{1}{p^2+(p\theta)^2}(Ip-\Gamma'p\theta)} \tag{26}$$

where $p\theta$ is a uniform rotation, a constant.

Comparing equation 20 with equation 8 it may be seen that the law of transformation of $\mathbf{p}^{-1}$ is the same as that of $\mathbf{p}$, namely

$$\mathbf{p}^{-1}=\mathbf{C}^{-1}\mathbf{p}^{-1}\mathbf{C} \quad | \quad p^{n}_{\cdot m'}=p^{m}_{\cdot n}C_{m'}^{m}C_{n}^{n'} \tag{27}$$

where along the stationary axes

$$\mathbf{p}^{-1}=p^{-1}\mathbf{I}=p^{-1}I_m^{\cdot n}.$$

Examples of the Physical Frame

SINGLE IMPEDANCES VIEWED FROM ROTATING AXES

For a single resistance, inductor or capacitor in each phase of the armature of an alternator, the individual impedance tensors along stationary axes are

$$\mathbf{R}=\begin{array}{c|cc} & \alpha & \beta \\ \hline \alpha & R & \\ \beta & & R \end{array}$$

$$\mathbf{L}p=\begin{array}{c|cc} & \alpha & \beta \\ \hline \alpha & Lp & \\ \beta & & Lp \end{array}$$

$$\frac{\mathbf{S}}{p}=\frac{1}{p}\begin{array}{c|cc} & \alpha & \beta \\ \hline \alpha & S & \\ \beta & & S \end{array} \tag{28}$$

The impressed voltage vector along stationary axes is

$$\mathbf{e}=\begin{array}{|c|c|} \hline e_\alpha & e_\beta \\ \hline \end{array}$$

Along uniformly rotating axes the impedance tensors of the individual coils become

$$\mathbf{R}'=\begin{array}{c|cc} & d & q \\ \hline d & R & \\ q & & R \end{array}$$

$$\mathbf{L}'\mathbf{p}=\begin{array}{c|cc} & d & q \\ \hline d & Lp & -Lp\theta \\ q & Lp\theta & Lp \end{array}$$

$$\mathbf{S}'\mathbf{p}^{-1}=\frac{1}{p^2+p\theta^2}\begin{array}{c|cc} & d & q \\ \hline d & Sp & Sp\theta \\ q & -Sp\theta & Sp \end{array} \tag{29}$$

The important fact should be noted that unilateral mutual impedances appear between the phases of an inductive or capacitive coil, as if they were two rotor phases of a rotating machine with magnetic or dielectric flux lines. The resistance tensor remains unchanged.

If the three coils of each phase are connected in series say when they represent a tieline with a series capacitor, the resultant impedance tensor becomes their sum

$$\mathbf{Z}'=\begin{array}{c|cc} & d & q \\ \hline d & R+\left(L+\frac{S}{p^2+p\theta^2}\right)p & -\left(L-\frac{S}{p^2+p\theta^2}\right)p\theta \\ q & \left(L-\frac{S}{p^2+p\theta^2}\right)p\theta & R+\left(L+\frac{S}{p^2+p\theta^2}\right)p \end{array} \tag{30}$$

The impressed voltage vector becomes

$$\mathbf{e}'=\begin{array}{c|c} d & q \\ \hline e_\alpha\cos\theta & e_\beta\sin\theta \end{array}$$

BALANCED 2-PHASE NETWORKS VIEWED FROM ROTATING AXES

The problem next is to replace the general tensor equations 20 to 22 by two sets of tensor equations, each relating to only one phase of a 2-phase system. The definitions of Γ, $\mathbf{p}$, and $\mathbf{p}^{-1}$ have already been replaced in equations 23 to 25.

Let the impedance tensor $\mathbf{Z}$ of a network with any number of meshes along phase α be the same as that along phase β. No mutual impedance is assumed between the two phases. Then along stationary axes the component impedance tensors are (expressed as compound tensors)

$$\mathbf{R}=\begin{array}{c|cc} & \alpha & \beta \\ \hline \alpha & R & \\ \beta & & R \end{array}$$

$$\mathbf{L}=\begin{array}{c|cc} & \alpha & \beta \\ \hline \alpha & L & \\ \beta & & L \end{array}$$

$$\mathbf{S}=\begin{array}{c|cc} & \alpha & \beta \\ \hline \alpha & S & \\ \beta & & S \end{array} \tag{31}$$

and the resultant impedance tensor, viewed from a stationary reference frame is

$$\mathbf{Z}=\begin{array}{c|cc} & \alpha & \beta \\ \hline \alpha & R+Lp+\frac{S}{p} & \\ \beta & & R+Lp+\frac{S}{p} \end{array} \tag{32}$$

where the index "α" includes all the meshes $\alpha_1, \alpha_2, \ldots \alpha_n$ along phase α, similarly the index β includes all the meshes β_1, β_2, $\ldots \beta_n$ along phase β.

The impressed voltage vector is

$$\boldsymbol{e}=\begin{array}{c|c} \alpha & \beta \\ \hline e_\alpha & e_\beta \end{array}$$

Let rotating axes $\boldsymbol{d}$ and $\boldsymbol{q}$ be introduced with the aid of

$$\boldsymbol{C}=\begin{array}{c|c|c} & d & q \\ \hline \alpha & \cos\theta I & -\sin\theta I \\ \beta & \sin\theta I & \cos\theta I \end{array} \qquad (33)$$

where I is the unit tensor. After transformation the matrices of $\boldsymbol{R}$, $\boldsymbol{L}$, and $\boldsymbol{S}$ happen to remain the same

$$\boldsymbol{R}'=\begin{array}{c|c|c} & d & q \\ \hline d & R & \\ q & & R \end{array}$$

$$\boldsymbol{L}'=\begin{array}{c|c|c} & d & q \\ \hline d & L & \\ q & & L \end{array}$$

$$\boldsymbol{S}'=\begin{array}{c|c|c} & d & q \\ \hline d & S & \\ q & & S \end{array} \qquad (34)$$

where now "$\boldsymbol{d}$" includes all the direct axes meshes $d_1, d_2, \ldots d_n$ and $\boldsymbol{q}$ includes all the quadrature axes meshes $q_1, q_2, \ldots q_n$. By equation 22 the resultant impedance tensor is

$$\boldsymbol{L}'\boldsymbol{p}=\begin{array}{c|c|c} & d & q \\ \hline d & Lp & -Lp\theta \\ q & Lp\theta & Lp \end{array} \qquad \boldsymbol{S}'\boldsymbol{p}'^{-1}=\frac{1}{p^2+p\theta^2}\begin{array}{c|c|c} & d & q \\ \hline d & Sp & Sp\theta \\ q & -Sp\theta & Sp \end{array}$$

$$\boldsymbol{Z}=\begin{array}{c|c|c} & d & q \\ \hline d & R+\left(L+\dfrac{S}{p^2+p\theta^2}\right)p & -\left(L-\dfrac{S}{p^2+p\theta^2}\right)p\theta \\ q & \left(L-\dfrac{S}{p^2+p\theta^2}\right)p\theta & R+\left(L+\dfrac{S}{p^2+p\theta^2}\right)p \end{array} \qquad (35)$$

Hence the effect of rotating axes is to introduce mutual impedances between each of the meshes of the two phases just as if each set of meshes were a rotating machine having both magnetic and dielectric flux lines.

It should be noted that the impedance tensor, equation 35, of any 2-phase network has the same form as that of two single meshes, equation 30, except that each scaler R, L, S is replaced by an appropriate tensor $\boldsymbol{R}$, $\boldsymbol{L}$, $\boldsymbol{S}$. This is another example of the Generalization Postulates facilitating the analysis of complex systems.

The impressed voltage vector is

$$\boldsymbol{e}'=\begin{array}{c|c} d & q \\ \hline \cos\theta e_\alpha & \sin\theta e_\beta \end{array}$$

EXAMPLE OF A 2-PHASE TRANSFORMER WITH CAPACITOR LOAD

To show an example where each of the phases has several meshes let the network on each phase consist of a 2-mesh transformer with a capacitive load as shown in Figure 1. Among the stationary axes of phase α the component impedance tensors are

$$\boldsymbol{L}=\begin{array}{c|c|c} & \alpha_1 & \alpha_2 \\ \hline \alpha_1 & L_1 & M \\ \alpha_2 & M & L_2 \end{array}$$

$$\boldsymbol{S}=\begin{array}{c|c|c} & \alpha_1 & \alpha_2 \\ \hline \alpha_1 & & \\ \alpha_2 & & 1/C \end{array}$$

and the resultant impedance tensor is

$$\boldsymbol{Z}=\begin{array}{c|c|c} & \alpha_1 & \alpha_2 \\ \hline \alpha_1 & r_1+L_1p & Mp \\ \alpha_2 & Mp & r_2+L_2p+\dfrac{1}{Cp} \end{array}$$

Then along the uniformly rotating axes the component tensors (still along one axes only) are

$$\boldsymbol{R}'=\begin{array}{c|c|c} & d_1 & d_2 \\ \hline d_1 & R_1 & \\ d_2 & & R_2 \end{array}$$

$$\boldsymbol{L}'=\begin{array}{c|c|c} & d_1 & d_2 \\ \hline d_1 & L_1 & M \\ d_2 & M & L_2 \end{array}$$

$$\boldsymbol{S}'=\begin{array}{c|c|c} & d_1 & d_2 \\ \hline d_1 & & \\ d_2 & & 1/C \end{array}$$

By equation 35 the transient impedance tensor of the resultant 2-mesh network along both axes is

$$\boldsymbol{Z}'=\begin{array}{c|c|c|c|c} & d_1 & d_2 & q_1 & q_2 \\ \hline d_1 & R_1+L_1p & Mp & -L_1p\theta & -Mp\theta \\ d_2 & Mp & R_2+\left[L_2+\dfrac{1}{C(p^2+p\theta^2)}\right]p & -Mp\theta & \left[-L_2+\dfrac{1}{C(p^2+p\theta^2)}\right]p\theta \\ \hline q_1 & L_1p\theta & Mp\theta & R_1+L_1p & Mp \\ q_2 & Mp\theta & \left[L_2-\dfrac{1}{C(p_2+p\theta^2)}\right]p\theta & Mp & R_2+\left[L_2+\dfrac{1}{C(p^2+p\theta^2)}\right]p \end{array}$$

STEADY-STATE EQUATIONS

If sinusoidal currents flow in the network and if their frequency with respect to the rotating reference frame is f then p becomes $jf\omega$, $p\theta$ becomes $v\omega$. Also if $\omega L = X_L$ and $S/\omega = X_c$ then along uniformly rotating axes the general equation 22

$$\boldsymbol{Z}=\boldsymbol{R}+\boldsymbol{L}\boldsymbol{p}+\boldsymbol{S}\boldsymbol{p}^{-1}$$

becomes

$$\boldsymbol{Z}_s=\boldsymbol{R}+jX_L(f\boldsymbol{I}-jv\Gamma)-jX_c\frac{f\boldsymbol{I}+jv\Gamma}{f^2-v^2} \qquad (36)$$

The 2-phase transient form, equation 35, becomes

$$\boldsymbol{Z}_s=\begin{array}{c|c|c} & d & q \\ \hline d & R+jfX_L-\dfrac{jfX_c}{f^2-v^2} & \left(jX_L+\dfrac{jX_c}{f^2-v^2}\right)jv \\ q & -\left(jX_L+\dfrac{jX_c}{f^2-v^2}\right)jv & R+jfX_L-\dfrac{jfX_c}{f^2-v^2} \end{array} \qquad (37)$$

If along the rotating axes the frequency is zero (as it is if the network is connected to a synchronous machine) $f=0$ and the above $\boldsymbol{Z}$ simplifies to

$$\boldsymbol{Z}_s=\begin{array}{c|c|c} & d & q \\ \hline d & R & -X_Lv-\dfrac{X_c}{v} \\ q & X_Lv-\dfrac{X_c}{v} & R \end{array} \qquad (38)$$

The Hypothetical Reference Frame

SYMMETRICAL COMPONENTS

In order to eliminate the unilateral mutual impedances between coils belonging to two different phases, symmetrical components (a set of hypothetical axes having no physical interpretation) are to be introduced along the physical $\boldsymbol{d}$, $\boldsymbol{q}$ axes. Let

$$\boldsymbol{C}_s=\frac{1}{\sqrt{2}}\begin{array}{c|c|c} & f & b \\ \hline d & I & I \\ q & -jI & jI \end{array} \qquad (39)$$

All tensors of valence two like $\boldsymbol{Z}$ are going to be transformed as

$$\boldsymbol{Z}'=\boldsymbol{C}^*{}_t\boldsymbol{Z}\boldsymbol{C}$$

Now the $\boldsymbol{R}$, $\boldsymbol{L}$, and $\boldsymbol{S}$ tensors of equation 34 remain unchanged. On the other hand the contravariant Christoffel symbol Γ, equation 23, assumes a diagonal form as

$$\Gamma=\begin{array}{c|c|c} & f & b \\ \hline f & jI & \\ b & & -jI \end{array} \qquad (40)$$

The absolute time-derivative $\boldsymbol{p}$, equation 24, and its inverse, equation 25, become also diagonal

$$\boldsymbol{p}=\begin{array}{c|c|c} & f & b \\ \hline f & (p+jp\theta)\boldsymbol{I} & \\ b & & (p-jp\theta)\boldsymbol{I} \end{array} \qquad (41)$$

$$\boldsymbol{p}^{-1}=\begin{array}{c|c|c} & f & b \\ \hline f & \boldsymbol{I}/(p+jp\theta) & \\ b & & \boldsymbol{I}/(p-jp\theta) \end{array} \qquad (42)$$

The transient impedance tensor, equation 35, becomes by equation 22

$$\boldsymbol{Z}=\begin{array}{c|c|c} & f & b \\ \hline f & R+L(p+jp\theta)+\dfrac{S}{(p+jp\theta)} & \\ b & & R+L(p-jp\theta)+\dfrac{S}{(p-jp\theta)} \end{array} \qquad (43)$$

showing the isolation of the two sequence equations. For a 2-phase transformer these equations become

$$\boldsymbol{Z}=\begin{array}{c|c|c|c|c} & f_1 & f_2 & b_1 & b_2 \\ \hline f_1 & R_1+L_1(p+jp\theta) & M(p+jp\theta) & & \\ f_2 & M(p+jp\theta) & R_2+L_2(p+p\theta)+\dfrac{1}{C(p+jp\theta)} & & \\ b_1 & & & R_1+L_1(p-jp\theta) & M(p-jp\theta) \\ b_2 & & & M(p-jp\theta) & R_2+L_2(p-jp\theta)+\dfrac{1}{C(p-jp\theta)} \end{array}$$

The couplings between the two phases have disappeared.

THE "ABSOLUTE" FREQUENCY TENSOR $\boldsymbol{n}$

If during steady-state the frequency of all currents with respect to the uniformly rotating reference frame is f then $p=jf\omega$ while $p\theta=v\omega$. Also $\omega L=X_L$ and $S/\omega=X_c$. Here f and v are fractions of the base frequency k in $\omega=2\pi k$ at which the reactances X_L and X_c happened to be calculated. The absolute time derivative $\boldsymbol{p}$ assumes the form

$$\boldsymbol{p}=\boldsymbol{I}p+\boldsymbol{\Gamma}p\theta=j\omega(f\boldsymbol{I}-jv\boldsymbol{\Gamma})=j\omega\boldsymbol{n} \qquad (44)$$

$$\boldsymbol{Z}=\begin{array}{c|c|c} & f & b \\ \hline f & R+jX_L(f+v)-\dfrac{jX_c}{f+v} & \\ b & & R+jX_L(f-v)-\dfrac{jX_c}{f-v} \end{array} \qquad (47)$$

where the "frequency tensor" $\boldsymbol{n}$ is defined along the hypothetical axes as

$$\boldsymbol{n}=\frac{\boldsymbol{p}}{j\omega}=f\boldsymbol{I}-jv\boldsymbol{\Gamma}=\begin{array}{c|c|c} & f & b \\ \hline f & (f+v)\boldsymbol{I} & \\ b & & (f-v)\boldsymbol{I} \end{array} \qquad (45)$$

Its physical interpretation is very important. It is built up of two components:

1. $-jv\boldsymbol{I}$ shows the speed (or frequency) of the reference frame with respect to the stationary conductors.

2. $f\boldsymbol{I}$ shows the frequency of the currents in the network with respect to the rotating reference frame assumed.

Hence their sum, the frequency tensor $\boldsymbol{n}$, shows the actual or "absolute" frequencies $\boldsymbol{n}$ of the currents in the conductors themselves. This property of $\boldsymbol{n}$ becomes very useful especially in the equivalent circuits of rotating machines where the conductors themselves are also rotating not only the reference frames. Knowledge of the frequencies of currents allows the determination of the torques of various frequencies. In terms of $\boldsymbol{n}$ the impedance tensors of equations 36 and 43 assume the form

$$\boldsymbol{Z}=\boldsymbol{R}+j\boldsymbol{X}_L\boldsymbol{n}-j\boldsymbol{X}_c\boldsymbol{n}^{-1} \qquad (46)$$

Comparing with equation 4 it may be seen that the equations of a stationary network remain unchanged if uniformly rotating axes are introduced and if in connection with them also hypothetical sequence axes are introduced. Only the frequencies entering into the equations have to be watched carefully, that is the scalar frequency n is replaced by the frequency tensor $\boldsymbol{n}$ (or the "absolute frequency" $\boldsymbol{n}$).

EQUIVALENT CIRCUITS ALONG THE ROTATING AXES

Since the equations $\boldsymbol{e}=\boldsymbol{Zi}$ of the armature axes of a synchronous machine equivalent circuit—to which the stationary network equivalent circuits are to be connected—have been divided by the frequency tensor $\boldsymbol{n}$, therefore all mesh equations of the stationary network also have to be divided by $\boldsymbol{n}$. Accordingly the impedance tensors of the equivalent circuits assume the form

$$\boldsymbol{Z}'=\boldsymbol{Rn}^{-1}+j\boldsymbol{X}_L-j\boldsymbol{X}_c\boldsymbol{n}^{-2} \qquad (48)$$

and the impressed voltages become

$$\boldsymbol{e}'=\boldsymbol{en}^{-1} \qquad (49)$$

The following two equivalent circuits will have to be then established:

1. For the steady-state networks $f=v$ hence $\boldsymbol{n}$ is v or $-v$

$$\boldsymbol{Z}_s=\begin{array}{c|c|c} & f & b \\ \hline f & \dfrac{R}{v}+jX_L-j\dfrac{X_c}{v^2} & \\ b & & -\dfrac{R}{v}+jX_L-j\dfrac{X_c}{v^2} \end{array} \qquad (50)$$

2. For the hunting network $j=h$ hence $\boldsymbol{n}$ is $h+v$ or $h-v$

$$\boldsymbol{Z}_h=\begin{array}{c|c|c} & f & b \\ \hline f & \dfrac{R}{h+v}+jX_L-\dfrac{jX_c}{(h+v)^2} & \\ b & & \dfrac{R}{h-v}+jX_L-\dfrac{jX_c}{(h-v)^2} \end{array} \qquad (51)$$

The negative sequence networks require negative resistances. The impressed voltages are

$$\boldsymbol{e}_s=\begin{array}{c|c} f & b \\ \hline \dfrac{\boldsymbol{e}_f}{v} & -\dfrac{\boldsymbol{e}_b}{v} \end{array}$$

$$-\Delta\boldsymbol{e}_h=\begin{array}{c|c} f & b \\ \hline -\dfrac{\Delta\boldsymbol{e}_f}{h+v} & -\dfrac{\Delta\boldsymbol{e}_b}{h-v} \end{array} \qquad (52)$$

The equivalent circuits (both steady-state and hunting) of three isolated coils and a transformer (to be connected to a synchronous machine) are shown in Figures 2(A) and 2(B). The equivalent circuit of a continuous transmission line is analogous to those of a transformer and is shown in Figure 2(C).

In view of the division by $\boldsymbol{n}$ it has to be remembered that the voltages (impressed or induced) on the equivalent circuits do not correspond to voltages in the physical networks, but rather to fluxes.

Industrial Plants Prefer Diesel-Electric Switching Locomotives

THOMAS J. WOODS
ASSOCIATE AIEE

DIESEL locomotives pulling long freight trains of several thousand tons on main-line railroads are a familiar sight, yet most people are not generally aware of the time and effort that must be expended in collecting and distributing this freight moving over the principal lines of the railways. The little known "workhorse" that performs the seemingly thankless task of collecting and distributing this freight to all industries is the switching locomotive, working at all hours of the day and night. Loaded cars are brought to a classifying point, where further switching and transfer work is required to "make up" a through freight train destined for movement over the main line.

Engines used in switching service may be classified broadly in two groups, depending upon ownership. A railroad switch engine is owned by the railroad and handles cars, not only on the railway property, but also in industrial plants where volume of traffic does not warrant the purchase of a locomotive. Industrial switch engines are used in many large plants for handling traffic within the plant or to a railroad exchange point. In many instances, the transportation system of an industrial plant may be larger and more complete than a fair-sized railroad, requiring, therefore, a large number of personnel for operation and maintenance of motive power.

To meet the specific requirements of this type of industrial service, there are many manufacturers who specialize in supplying industrial plants and railways with these smaller switching locomotives, weighing 80 tons or less, with horsepower ratings up to 600. Main-line locomotives are much larger and have been built in capacities of 500 tons and several thousand horsepower. These are specialized fields and usually are handled independently by different builders.

Development of the Diesel Engine for Railway Service

For many years the reciprocating steam locomotive handled practically all the transportation services in industrial plants. Little thought was given to the diesel engine which was proving itself to be an efficient and economical prime mover for stationary work, but these cumbersome slow-speed units were totally unsuited for railway vehicles. By 1925 it began to be recognized that the diesel engine offered considerable possibilities as a prime mover for locomotives; developments incorporating higher speeds, lower weights of parts, and more power concentrated in a small space were under way. In a comparatively few years—the early thirties to be exact—the diesel engine rapidly grew in popularity as a prime mover for railway work. Today, it enjoys a dominant position in the motive power field. The large percentage of locomotives now being ordered are of the diesel type. On December 1, 1948, there were 1,615 diesel locomotives on order for delivery to Class I railroads, as compared to 78 steam locomotives.

Electric Transmission

To the electric transmission can be traced the success of the diesel engine as a prime mover for locomotives. Locomotives must deliver high pulling capacity at low speeds and high horsepower at high speeds. As the engine is a relatively constant torque device, it cannot meet these conditions and, therefore, is not suited for a locomotive propulsion drive without the introduction of a torque-converting mechanism between the engine and driving wheels. The d-c generator and traction motors (the electric transmission) between engine and wheels are unsurpassed as a torque converter. The relatively unvarying torque of the diesel engine is converted to the correct type of power required at the driving wheels. This ranges between the high torque, sufficiently great to slip the wheels at starting, to the low torque values at high speed. In other words, the electric transmission permits utilization of full engine horsepower over the operating-speed range of the locomotive. Locomotive builders have available reliable and efficient electric transmissions, designed for

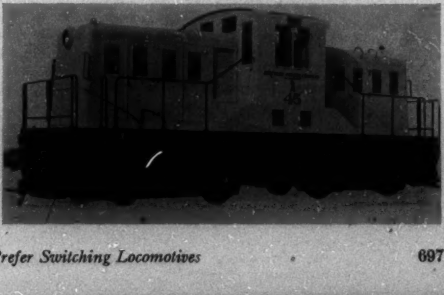

Figure 1. 65-ton 500-horsepower industrial switching locomotive with four traction motors

Paper 49-176, recommended by the AIEE Land Transportation Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer General Meeting, Swampscott, Mass., June 20–24, 1949. Manuscript submitted March 22, 1949; made available for printing May 3, 1949.

THOMAS J. WOODS is a Transportation Engineer in the Industry Engineering Department of Westinghouse Electric Corporation, East Pittsburgh, Pa.

the severe service encountered on locomotive applications and suitable for all sizes of locomotives. These electric machines present difficult design problems because of space limitations. To achieve required ratings in the limited space, not only are high-strength materials used, but it is also necessary to work the machines at temperatures well beyond those found practicable for stationary industrial applications.

Present Status of Diesel Motive Power

As the prime mover for a switching locomotive, the diesel engine is unsurpassed. It is efficient, uses a minimum of fuel, presents no water and ash problem, and has low standby losses. With electric transmission, it is possible to easily power any number of driving wheels to obtain high pulling capacity. So outstanding is the diesel-electric locomotive in these respects that it is rapidly replacing the steam locomotive for switching service. Practically no steam switching units are being built at present. As an indication of the rapid growth in popularity of diesel-electric motive power, Table I shows the cumulative total of small diesel locomotives sold through 1948.

Standard Locomotive Sizes

Industrial switching locomotives usually range in size from 20 up to about 80 tons on drivers. In a few large industrial plants, however, such as certain steel mills, 120-ton locomotives, commonly found in railway switching, are required to handle the heavier loads encountered. For the great majority of applications, it bears repeating that units of less than 80-tons weight are entirely adequate.

From the extensive application experience gained in this country and abroad, there has evolved a line of standard units suitable for industrial work. These are classified by weight on drivers. The most common types are the 25-, 35-, 44-, 50-, 65-, and 80-ton locomotives. There is a sufficient degree of flexibility in design of these locomotives to permit builders to supply locomotives with characteristics to meet special operating requirements of users. These special requirements are many. Both in this country and abroad, other than standard gauge is frequently encountered; also, unusual width and height limitations often are imposed.

Table I. Diesel Electric Locomotive Sales

Up to 80 Tons on Drivers

Year	Number of Units, Cumulative
1935	27
1940	213
1945	1,966
1948	2,500

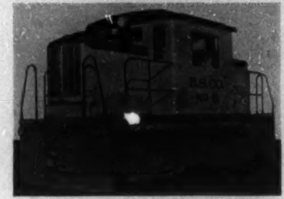

Figure 2. 50-ton 300-horsepower industrial switching locomotive with two traction motors

With the many types of engines and electric apparatus available, the locomotive builders have been able to supply industrial users with the required locomotive sizes and characteristics.

With industrial locomotives varying in weight from 20 to 80 tons, it is interesting to note that locomotives of about 50 tons weight have proved the most universally acceptable for plant switching. Following is a list of the percentage of locomotives sold with respect to weight on drivers. This includes all industrial-type locomotives under 80 tons weight sold through December 31, 1948.

Weight on Drivers, Tons	Per Cent of Total Sales
Below 20	3
21–30	10
31–40	3
41–50	49
51–60	3
61–70	24
71–80	8

Engine–Generator Sets

The builders of industrial locomotives do not manufacture diesel engines but purchase recognized makes for locomotive installation. These range in speed from 1,000 to 2,100 rpm and in horsepower from 100 to 600. In recent years, as engine design and reliability have improved, the trend has been toward higher speeds. A number of 2,100-rpm engines of 250 to 300 horsepower have been in service for several years with excellent operating results. In engines of 600-horsepower capacity, operating speeds of 1,000 to 1,200 rpm normally are not exceeded.

A single-bearing traction generator is recognized as the most acceptable for locomotive service. Coupling details vary. Many types of generators utilize a solid coupling between the armature and the crankshaft. On others, a steel-disc flexible coupling is used, with the generator frame bolted to the engine through a machined-fit bell housing. Either method of mounting results in a compact unit free from distortion caused by locomotive movement.

Traction Motors

Two types of traction motors are available for locomotive use—the heavy slow-speed type with the integral axle bearing using a single reduction gear, and the light-weight high-speed type utilizing multiple-reduction gearing. Careful analysis of service requirements will indicate which is better suited for a particular service. The slow-speed motor has a maximum speed of 2,000 rpm, as compared to 4,500 rpm for the high-speed motor. The following tabulation indicates the principal characteristics of each when geared for the same continuous tractive force.

	Motor Type	
	Slow Speed	High Speed
Weight, pounds	4,200	1,425
Rated tractive force, pounds	5,500	5,500
Gear ratio	4.4-to-1	22-to-1
Maximum locomotive speed, miles per hour	50	20

It is evident that the high-speed motor may be geared for the same continuous tractive force as the heavier slow-speed motor. This is done at a sacrifice in maximum locomotive speed. Under the stated conditions, a locomotive using the large low-speed motor is permitted a maximum speed of 50 miles per hour, while the smaller high-speed motor limits the maximum speed of the locomotive to 20 miles per hour. For industrial plants where the locomotive is restricted to slow-speed operation, the smaller motor is well suited. The thermal capacity of this motor is less than the heavy motor, resulting in a lower short-time rating. By proper consideration of axle loading and service requirements, it is possible to use the lightweight motor on locomotives requiring 25 to 35 miles per hour maximum speed.

Comparative Performance of Steam and Diesel-Electric Locomotives

One of the principal reasons the diesel-electric locomotive is supplanting the steam locomotive in industrial switching is its superior operating characteristics.

The operating cycle of a locomotive in switching service is short. It consists of accelerating from standstill up to approximately 10 miles per hour, then braking to a complete stop. The next operation may be in the reverse direction. As the time element is important, it is essential that the locomotive have the ability to respond quickly to throttle manipulation and to develop high tractive force at low speeds, in order to produce a high rate of acceleration. With an electric control system, the diesel responds to control manipulation faster than a steam engine of comparable size. The steam engine has a pulsating torque characteristic; the torque at the driving wheels of the diesel-electric is smooth. It has been found that the steam engine cannot be operated in excess of about 25 per cent adhesion; the diesel locomotive has a starting tractive force based on 30 per cent adhesion. Thus, with the same weight on drivers, the diesel has a starting tractive force 20 per cent greater than the steam engine, resulting in a higher rate of acceleration so necessary for switching service. The accelerating rate of the steam engine is further reduced by the nonadhesive weight carried on the tender and idle axles of the locomotive.

The diesel locomotive, with electric drive, is particularly well suited for short heavy-grade operation, often encountered in industrial plants. These grades may be in the form of ramps and may be quite steep. With the inherent ability of the electric equipment to withstand heavy overloads for short periods of time, the diesel locomotive may be worked up the short grade at tractive-force values approaching the slipping point of the wheels, and, for the reasons before mentioned, would excel a reciprocating steam locomotive of equivalent horsepower rating.

Most industrial plants do not require all locomotives to operate 24 hours a day. During the off period the diesel locomotive may be shut down and housed for the night. With the steam engine, there is the ever-present problem of maintaining fires. This may require additional personnel for the sole purpose of keeping the locomotives fired, thus adding to the cost of maintaining the transportation system.

Higher economy and greater availability are the principal factors sounding the "death knell" for the steam switching locomotive. Smoke-control ordinances of many communities merely increase the preference for diesel electrics. Although some progress is being made in reducing smoke from steam locomotives by using overfire air jets and controlled combustion, it is unlikely that the steam locomotive will ever be as clean as a diesel.

Table II. Comparison of Operating Costs of Steam and Diesel-Electric Locomotives Typical Steel Plant

	Dollars Per Hour	
	Present Steam	50-Ton Diesel
Fuel	$ 0.698	$ 0.330
Lubricants	0.045	0.033
Water	0.032	.....
Supplies	0.073	0.040
Repairs	1.272	0.350
Total	$ 2.120	$ 0.753
Hours per year	13,660	13,660
Annual operating expense	$28,959	$10,286
Annual operating savings by use of diesels		$18,673

Economies of Diesel Motive Power

In these days of increasing costs, efficiency is becoming increasingly important as premiums are set on economy of operation. From the standpoint of efficiency, the diesel switching locomotive is unexcelled. In most instances a considerable saving in operating expense results by the substitution of diesel power. A careful analysis of a switching service will indicate the advisability of replacing existing steam power with diesel-electric locomotives. The decision to substitute diesels for existing steam motive power usually depends on the number of hours the diesel may be used. The modern diesel locomotive has an availability of about 90 per cent, and it is desirable that it be utilized to the fullest extent in order to realize the greatest savings. For example, in a small plant requiring only eight hours of switching per day, it may be impossible to realize a sufficient saving in operating cost to justify the large expenditure for a diesel locomotive. In general, it may be said that a diesel will justify its purchase price if it can be used a minimum of 10 to 14 hours per day.

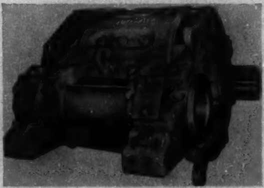

Figure 3. Axle-hung traction motor for 65- and 80-ton diesel-electric locomotive

The items of operating expense in which a diesel shows the greatest savings are fuel and repairs. With present prices of coal and diesel fuel, the diesel locomotive can do the same amount of switching work as a steam locomotive with 25 to 50 per cent of the fuel cost. There is a fixed relation between the coal burned in a steam engine and the fuel oil used in a diesel locomotive for a particular service. In switching service, this ratio is 100 to 140 pounds of coal to one gallon of diesel fuel. This variation is due to the difference in types of switching service, which is ascertainable by observation. The selling price of fuel oil and coal in a particular locality will cause further variation in relative fuel costs.

Data obtained from various operating companies indicate that diesel repairs average 30 to 50 per cent of comparable steam repair costs. A general figure for diesel repair expense cannot be established for a particular size diesel locomotive. This is particularly true in industrial plant switching. The repair expense has been found to vary greatly, depending on local conditions. With relatively few locomotives in service, for example, maintenance personnel must be retained even though they are not needed at all times. This results in a high repair expense chargeable to the locomotives. On the other hand, if there is a relatively large number of locomotives on the property, by proper scheduling, the unit repair expense will be low. It has been established, however, that on a particular property, there will be a definite relationship between maintenance costs for steam and diesel locomotives. If the steam repair costs are low because of efficient maintenance, then the diesel repair costs likewise will be low when diesel substitution is made. Taking these factors into consideration, it is possible to estimate with a considerable degree of accuracy the economic justification of diesel motive power.

To illustrate what may be accomplished by the substitution of diesel motive power, the results of a recent steel-mill-application study are shown in Table II. The mill has five steam locomotives in operation handling intraplant switching. Consideration is being given to the replacement of these units with diesel locomotives. An analysis of the system indicates that four 50-ton diesel-electric locomotives can replace existing steam power. The resulting savings will pay for the diesels in five to seven years. It may be seen that each diesel locomotive will average 3,415 hours of operation per year, and the annual savings in operating expense will approximate $18,673.

Conclusions

The position of the diesel-electric locomotive in the industrial-switching field is unchallenged, as evidenced by the large number in service and the rapid rate at which existing steam power is being replaced.

The versatility of this form of power is well suited for the many applications encountered ranging from heavy steel-mill work to light switching in small industrial plants.

The operating advantages and economies possible with diesel locomotives are obtainable by precision maintenance and repair. A diesel-electric locomotive is composed of many elements, requiring trained personnel for its proper upkeep and for realizing the high availability and low operating cost inherent in this type of motive power. A diesel locomotive functions best when properly maintained. By observing the necessary precautions with regard to operation, following recommended maintenance procedures, and keeping the locomotive equipment clean, the industrial user will achieve an economy of operation hitherto unattainable with reciprocating steam motive power.

No Discussion

Improvements to Oklahoma City Primary Network

BRYCE BRADY
MEMBER AIEE

Synopsis: The expansion of an existing 4.16-kv primary network in Oklahoma City has been found to be more economical than conversion to a radial plan of primary distribution. Some recent improvements are described; some operating problems are discussed.

THE SECOND oldest primary network in the United States has provided service to a typical residential section of Oklahoma City since 1931. When load growth recently made it apparent that major improvements would be required, a study was made to ascertain whether it would be more economical to retain and expand the network or to convert to a radial primary system such as is used in all other sections of Oklahoma City where the load density is of similar magnitude.

Premises

Load growth was projected three times its present magnitude, and both radial and network systems were designed to serve this future load. Every effort was made to keep the two plans as nearly comparable as possible. Service to all customers in both plans was made firm to the extent that loss of one 13.8-kv source line must not cause an outage, and that the overload on the remaining substation transformers and equipment shall not exceed 150 per cent. Both plans assume that sufficient capacitors will be added to the distribution lines from time to time to maintain approximately 0.90 power factor at peak load. Both plans include conversion from the present uniground neutral system to a common primary-secondary multiground neutral system.

Radial Plan

The radial plan proposes the installation of one centrally located substation to serve the entire area, which ultimately will consist of two 6,000-kva 3-phase transformers; six 4.16-kv outgoing feeders, each with reclosing circuit breaker and step-type voltage regulator; and three incoming 13.8-kv lines, with switches to isolate any faulted line. The 13.8-kv lines also would serve other load in adjoining areas. In order to limit the available fault current through the voltage regulators, the 4.16-kv bus would be split and would have an automatic tie breaker; that is, each 6,000-kva transformer normally would serve three outgoing 4.16-kv feeders. All load, however, would be switched automatically to the remaining transformer in case of transformer or 13.8-kv bus failure. This ultimate plan provides firm service to 9,000 kva of load. Of course, the necessary expenditure for the individual components would be deferred until required to serve the growing load.

Network Plan

Comparative cost estimates were prepared for various numbers, sizes, and arrangements of network stations. It was found that the most economical plan which would provide firm service to 9,000 kva of load, distributed according to the load forecast, would consist of four network substations, interconnected by five 4.16-kv mains and served by three 13.8-kv source lines. The two substations served by the same 13.8-kv source would not have a 4.16-kv tie main between them. The 13.8-kv lines also would serve other load. Each of the network stations was planned with tap changing under load-bus regulation—one master circuit breaker, and either two or three feeder circuit breakers as required. All automatic switching is to be done at 4.16 kv. Each component of expenditure would be deferred until required.

Economic Comparison

Cost estimates were made of both network and radial plans to provide firm service year by year during the next 17 years under assumed load growth conditions. These estimates show that the network plan will require less capital expenditure than the radial plan for improvements to the present system, both immediately and ultimately. The estimates compare as follows:

	Network	Radial
Immediate capital expenditure, per cent	100	114
Ultimate capital expenditure for 9,000-kva load, per cent	128	144

This comparison does not include cost of losses, nor does it recognize the different years during which improvements would be required. Evaluation of copper and iron losses shows an additional difference in favor of the network plan, by virtue of the decreased average distance from substations to load. The present worth at 6 per cent interest of the immediate and future capital expenditures plus the future copper and iron losses during the next 17 years compare as follows: If retention of the network plan, including losses, is taken as 100 per cent, then conversion to the radial plan under the same conditions is 134 per cent.

It must be remembered that these comparisons do not pertain to the establish-

BRYCE BRADY is Chief Distribution Engineer of the Oklahoma Gas and Electric Company, Oklahoma City, Okla.

ment of a new primary network. They pertain to the alternatives of retaining and adding to an existing primary network, versus the conversion of this existing network to a radial system.

Operating Comparison

Service continuity has been equal to or slightly better during the last 17 years in the network area than in comparable radial areas. It is difficult to predict the future trend because of improvements that currently are being made in both the radial and network service areas. A carefully co-ordinated scheme of line-sectionalizing fuses and instantaneous and very-inverse-time-delay relays is being installed on all 4.16-kv radial circuits which, it is anticipated, will very materially improve service continuity to all customers. It does not appear that this plan of automatically ascertaining whether a fault is transient or permanent, and using fuses for automatic sectionalization in the latter event, can be applied to the network plan. Principally for this reason, it may work out that service continuity will be slightly better in the radial service areas in the future. Only time will answer this question.

Most of the operating difficulties on the primary network have arisen from the fact that two of the network stations are served directly from a generating station while the third network station is served from a 66-kv substation, with somewhat different phase angle at various hours of the day. This has resulted in some improper circuit breaker operations. These have not, in general, resulted in customer outage, but rather in pumping action and transfer of load between network stations. This problem has been serious but not insurmountable. Various solutions have been used, including reversal of the reactance setting of the line-drop compensators and desensitization of the network relays. The plan which is being used now and which appears to be the most satisfactory, is a network relay scheme whereby a network station is disconnected from source when the load current either reaches zero or reverses, and is restored to service when the source voltage is both higher in magnitude and leading in phase angle. At the present time, the reactance settings of the line-drop compensators are set on zero at two network stations and are reversed on the other two. Positive overcompensation of voltage drop, that is, delivery of higher voltage at peak load, then at light load, is accomplished solely with the resistance setting of the line-drop compensators.

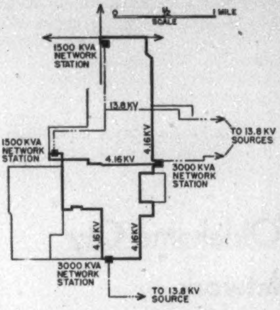

Figure 1. Oklahoma City primary network at present stage of development

The network and radial plans were kept comparable on the basis of voltage spread between first and last customer at the time the comparative cost estimates were prepared. There is no reason why this should not continue to work out in practice.

It is necessary to add supplementary sectionalizing devices on long radial extensions from the network ahead of the point where the available fault current would fail to actuate the circuit breakers, just as on a radial system. These devices may be either repeating fuses or pole-top reclosers.

Recent Improvements

As a result of this investigation, two 3,000-kva unit-type network stations of the factory-assembled-type have been purchased and are now in operation. Both of the stations were installed in well built-up residential areas and are located on lots immediately adjacent to residences. In one case we were able to secure a vacant lot; in the other case this could not be done, and we purchased a lot with a frame house, which dwelling was sold and removed. The feeders leave the new stations via 500,000 circular-mil paper-insulated lead-covered cables in underground ducts. All of the remainder of the 4-kv system is overhead and is illustrated in Figure 1. The mains are predominantly number 000 bare copper and 267,000 circular-mil bare aluminum without steel reinforcing. The laterals are predominantly number 6 hard-drawn copper and number 4 aluminum-cable-steel-reinforced conductor. The 13.8-kv connection to one of the new stations is overhead; to the other, underground. Each of the new stations will be landscaped with shrubbery and grass by spring 1949 to minimize any objection by those who live nearby.

Conclusions

The 4.16-kv primary network is a satisfactory and economical method of distributing electricity. Its relative economy depends upon the proximity of a suitable number of subtransmission voltage sources and the relative cost of extending these versus 4.16-kv feeders. In some cases it may be considerably more economical than a radial system made equally firm and reliable. All of the supply lines to a primary network should originate at one firm source, or from sources which do not have appreciable phase-angle differences. The relaying of primary networks is much more complicated than on radial systems. The copper loss on a primary network is considerably less than on a radial system, because energy is transmitted nearer to the load at high voltage, and because more advantage is taken of load diversity. Unit-type substations can be added near the load center of well built-up residential and commercial areas without excessive costs. There is probably no great difference in the quality of service rendered by a primary network as compared with radial feeders. It is anticipated that the radial circuits which are being equipped with sectionalizing fuses carefully co-ordinated with instantaneous and time-delay relays to secure automatic sectionalization of faults, will provide somewhat better service continuity than the primary network.

Discussion

H. E. Campbell (General Electric Company, Schenectady, N. Y.): It is gratifying to see the author's conclusion that the 4.16-kv primary network is a satisfactory and economical method of distributing electricity. This confirms our thoughts about the primary network system.

The author points out that he has experienced some difficulty in pumping action of the transformer circuit breakers and he found it necessary to desensitize the network relays. Is it possible that his difficulty could have been avoided if a less sensitive relaying scheme had been used in the beginning? And, would not a less sensitive relaying scheme make it unnecessary to conclude that all of the supply lines to a primary network should originate at one firm source or from sources which do not have appreciable phase angle differences?

If directional overcurrent relays, set to trip for currents of 100 per cent in the reverse direction, were used instead of the sensitive network relays, then some phase angle differences can be tolerated without any expected difficulty. As long as the magnitude of the power flowing out of the network is not great enough to overload any part of the network, there should be no objections to such a transfer of power.

The stipulation that all primary network substations be supplied from one firm source seems to be an economical hardship placed upon this type of system. Quite often sources of power for a primary network can be found at many locations throughout an area. If these cannot be tapped because of sensitive relaying, then subtransmission cost for the system might be excessive.

We have not considered it necessary to use sensitive relaying in order not to have an occasional power reversal through a network substation. We would appreciate the author's comments on this.

Bryce Brady: We agree with Mr. Campbell that there is no harm in having reverse current flow from the primary network, through a network station, into a source line under normal operating conditions.

Our concern is for the safety of the public under abnormal conditions such as with a broken conductor on a 13.8-kv source line. It is considered imperative that the network switch be opened to stop the back-feed into such a fault. All of our network transformers are connected delta on the 13.8-kv side and wye on the 4.16-kv side, and therefore deliver very slight current into this type fault.

While there are other methods of detecting line-to-ground faults, such as grounding potential banks, Thyrite ground indicators, and "over-and-under" voltage devices, we have found the modern network relay to be the most dependable. We set this relay to open the switch when load current either reaches zero or reverses, and to close the switch when the source voltage is both higher in magnitude and leading in phase angle.

This scheme, together with the reversal of the reactance settings of the line drop compensators, has apparently stopped all pumping action and transfer of load between stations, which action was quite bothersome some years ago.

Primary Networks on the Duquesne Light Company System

ASSOCIATE AIEE

THE 4-kv primary-network type of distribution system is used successfully in the Pittsburgh area. This is not a new development. In fact the design of the Verona–Oakmont 4-kv network, which was placed in service in 1931, was reported and described in considerable detail in a paper published in September, 1931.[1]

A report[2] of the first year of operating experience with this network system was presented in November 1932. A new feature was added to improve stability, to reduce circulating currents, and to reduce transformer circuit-breaker operations. The application of inverse reactive compensation to the induction voltage regulators provided a solution for these problems.

These two important contributions to technical literature provide a historical background for the primary network on the Duquesne Light Company system, and also have become a record of achievement in distribution engineering.

It is the purpose of this paper to present results of recent tests of the Verona–Oakmont network and to provide a 1931–1948 performance record. A new 4-kv primary-network installation for the Squirrel Hill area also will be discussed, with special reference to present-day practices and modern equipment that now is offered by manufacturers of distribution substation equipment.

Summary

1. Test results and operating experience confirm the effectiveness of inverse reactive compensation to provide satisfactory division of load between network units, to improve stability, and to reduce the circulating currents.

2. An 18-year performance record for 1931–1948 of the Verona–Oakmont 4-kv primary-network system provides convincing evidence of a high degree of service reliability.

3. The primary network is attractive from a system cost point of view, provided conditions in the area to be served include reasonably uniform load density, substantial overload relief requirements, and the need for a high degree of service reliability.

4. The interconnected mains between network substations, which provide 2-way service to all loads, permit circuit breaker or transformer maintenance without prearranged switching or outage to any customers. Only extended unit outages require the use of the mobile unit substation.

5. The Squirrel Hill network is equipped with modern network units of the factory-built package type. These units will be cable connected and completely metal clad, and have been selected with consideration for economical size. Other features include regulation by means of automatic tap changing under load with inverse reactive compensation and 4-kv air circuit breakers. All network units are installed outdoors with fenced enclosures.

Operating Elements of the Verona–Oakmont Network

Figures 1, 2, and 3 show the electrical and geographical arrangement of the network station units, the 4-kv circuits, the 22-kv subtransmission circuits, and a single-line diagram of the station equipment.

The network, which remains effectively the same as at installation, has three transformer units, each with a nameplate rating of 1,500 kva, which transform the voltage from 22 kv to 4 kv. The five network mains interconnecting these three units are 1/0 open-wire lines with cable connections to circuit breaker cubicles at the network substations. The 22-kv single radial connections to the network units are made with open-wire line extensions and underground cable to a 3-position switch on the network transformers. Each unit has a 4-kv bank circuit breaker and three single-phase induction bus regulators. The Hulton and Verona units each have three feeders or mains connected to the bus by oil circuit breakers, and the Oakmont unit has four feeders or mains and four oil circuit breakers.

The bank circuit breakers are equipped with network and reclosing relays; the transformers, with contact-making thermometers. The feeders are tripped by induction overcurrent relays and reclose automatically, once from each end, with the reclosing times staggered. The 4-kv bus is provided with differential protection using induction overcurrent relays.

For the purpose of obtaining experience with various types of installation, one unit was installed underground, one in a small building, and one outdoors. The transformer and regulator housing construction in all three is essentially the same. They were designed to be watertight units with wiped cable entrance connections. The circuit breakers in Hulton also were designed to be watertight, while those at Oakmont and Verona were designed as weatherproof cubicles. All the watertight equipment has removable flat plates held by nuts on stud bolts, gasketed with flat cork gaskets.

The regulators are induction type with a five per cent plus or minus regulating ability. They are equipped with the

The authors gratefully acknowledge the important contributions of G. N. Hoffman and L. M. Olmsted to this paper.

normal regulator control, except that the reactance section of the compensator has been reversed by changing connections internally.

Supervisory indications are transmitted to the System Operator's office to provide immediate information of abnormal operating conditions, such as open circuit breakers, high transformer temperature, control voltage failure, and deenergized station.

Some time after installation, the Hulton unit, which is underground in a vault, was equipped with additional control facilities located just under the street-level grating, so that manual operations could be performed even though the equipment was submerged. This unit also is equipped with a pump controllable from the grating opening and a hose connection at the same level, so that water can be discharged into the street.

Operating Experience

The annual peak loads from 1931 to the present time are shown in Figure 4, along with the adjustments of the contact-making voltmeter and voltage compensator. The network nameplate capacity of 4,500 kva was provided for an estimated 2,000 kva of load. Actually, because of conditions existing in the early thirties, the load did not reach this point until 1936. Now it is almost 4,000 kva, and because of the relatively large capacity originally installed, it has not been necessary to increase the number of units or the size of the transformers. Recent tests and studies resulted in an increase in the assigned capacity of the network, based on thermal capabilities, and further tests are expected to result in another increase in capacity ultimately. A study also is being made relative to the addition of a fourth unit.

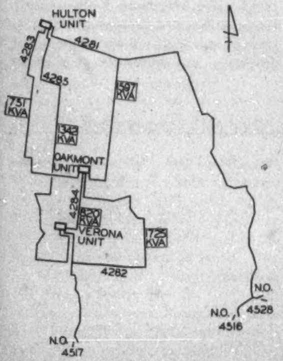

Figure 1. Verona–Oakmont network: map showing network units, 4-kv mains, and connected loads

The original inverse reactive compensator setting of 20 was determined by test and later raised to 24 because of a change in current-transformer ratio. Early experience indicated the impracticality of operation without this inverse reactive compensation. The regulators at the three units assumed widely divergent positions, and, as a result of the tendency of the bus voltages to be unequal, circulating currents of relatively high value occurred. At light load periods, this was sufficient to cause one of the unit-bank circuit breakers to trip repeatedly on current fed back into the transmission system from the other two units.

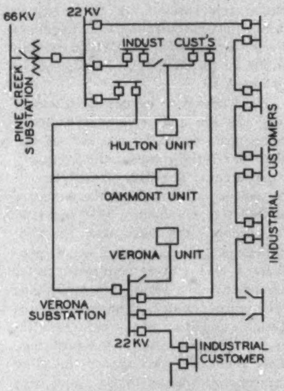

Figure 2. Verona–Oakmont network: schematic diagram of 22-kv connections

Theoretically, the highest inverse reactive compensation available that would not cause hunting would be desirable, since the current due to the tendency to different bus voltages would be held to a minimum; that is, a very small reactive current flowing would produce enough voltage at the contact-making voltmeter to cause it to change the regulator position to stop this flow, but not change it enough to reverse the flow. Another factor requires consideration, however. The reactive component of the load current will lower the entire network voltage, and, unless there is sufficient resistance compensation available to overcome this effect of the reactive load component and add whatever additional voltage is desired, a compromise setting must be used.

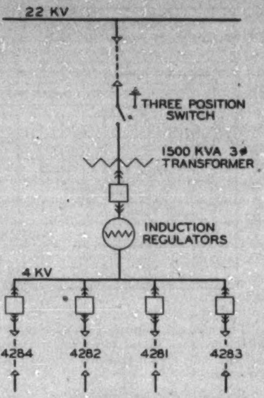

Figure 3. Verona–Oakmont network: schematic diagram of a network unit

With the relatively light loads of the first several years of operation, it was thought unnecessary to have any resistance compensation in the circuit. However, as loads increased, it became necessary to add resistance compensation to prevent lowering of the 4-kv bus voltage due to the effect of the reactive component of load, as previously explained. The present relation of reactive to resistance compensation of two-to-one will provide a constant bus voltage with a load power factor of 90 per cent.

All of the inverse-time feeder relays are set at the same pick-up and time values. Calculations of current division between the circuits during fault conditions indicated that sufficient time selection would be obtained to insure co-ordination. Operating results show satisfactory co-ordination, in that no feeders have tripped incorrectly during faults on other feeders. Clearing of faults on network feeders usually will be by sequential opening of the two ends of the feeder and will require, therefore, longer time than on radial feeders.

The operating experience with the unit in the underground vault has not been entirely satisfactory for the following reasons:

1. It is difficult to maintain watertight seals with flat gasketed plates that are removed frequently for testing, maintenance, and operation.

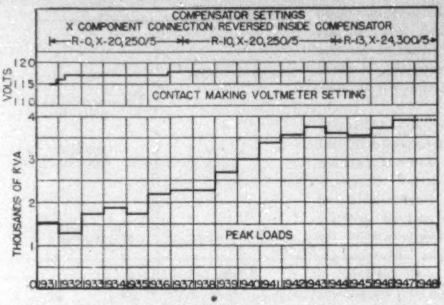

Figure 4. Peak loads, compensator settings, and contact-making voltmeter settings, 1931–1948

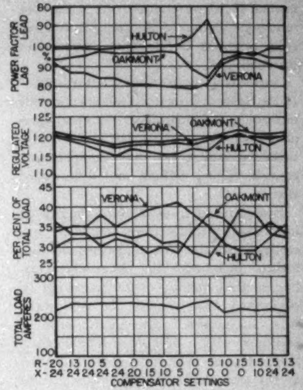

Figure 5. Effect of changes in compensator settings on load division, regulated voltage, and power factor of load current

2. Two men are required for work that one switchman does at all other nonattended stations. One man is required to guard the entrance.

3. Corrosion, dirt, and moisture are deteriorating the equipment in this unit more than at the two surface units.

4. It is necessary to tear up the street and interfere with traffic to effect removal and installation of major equipment.

It is recognized that improvements can be made that would minimize the above conditions. The experience has been, however, that this equipment cannot be maintained in the manner that surface-installed equipment is maintained.

Test Results

Figure 5 shows results of tests to determine the effect of compensation settings on operation of the network. These data indicate that the present settings of 13*R* and 24*X* produce satisfactory results and about the best combination of load division, voltage, and power factor for the conditions encountered. The power factor at time of test was higher than 90 per cent; the regulated bus voltage is correspondingly higher than the balance point.

The effect of increasing the inverse reactive compensation on the regulated voltage is clearly shown, as is the use of the resistance compensation in compensating for the undesirable lowering of bus voltage level.

The tendency to increase unbalance of load current and amount of reactive component carried by the various stations, as reactive compensation is cut out, is apparent. The data plotted for the 0–0 compensation setting is the average of several sets of readings that were obtained during this test setup. The regulators changed position and the distribution of load current and power factor among the units varied during the time this setting existed, demonstrating the unstable condition of the network without the inverse reactive compensation. This would be accentuated if the 22-kv transmission sources to the units were less solidly connected than they are in this installation.

The charts in Figure 6 indicate load current division with various operating conditions of the network. The tests in which the tie main between Verona and Hulton was open, were made to simulate conditions that would occur on a network where there would not be direct mains between each unit and each other unit. In one test the regulators at Verona were manually set in the neutral position with the main between Verona and Hulton open, to determine load division if the mobile substation unit, which is not regulated, were used in place of a regular network unit. The possibilities encountered under abnormal operating conditions are so numerous that general tests can provide only a general indication of what would take place. The number of units in the network, number of tie mains between units, impedance of these mains, compensation, and firmness of the high-tension sources all will contribute to the division of load under abnormal condi-

tions. It appears that manual setting of regulators may be required to provide the distribution of load desired to prevent overloading some units, under conditions of a unit outage during peak load periods, where total load approaches total remaining load capability.

Network Performance: 1931-1948

Table I shows the outages to the network units and tie mains from all causes. The figures include both accidental or fault outages and planned or maintenance outages to the units. The outages to the tie mains are all caused by faults. The blank spaces indicate that no data were available for those periods.

During the 18 years of operation, there have been nine complete network outages. Three occurred during the following major system disturbances: generating-station bus failure, flood, and failure of a tie-line transformer on a circuit feeding this area radially during labor trouble in 1946. One network outage was caused by a fault on the 22-kv line which supplies Hulton. This line contacted a 4-kv circuit, with the result that Oakmont and Hulton bank circuit breakers opened due to current flow to the grounded neutral of the banks. The other five outages occurred when the four 22-kv transmission lines which energize the network were out of service simultaneously due to sequential faults and cross feed operations. During storms, lines became temporarily faulted, and because there was no automatic reclosing equipment at customer stations adjacent to Verona, a succession of these operations caused a complete outage. The installation of automatic reclosing at these adjacent stations, and various other improvements, reduced this type of operation to a point where it has occurred only once since 1936.

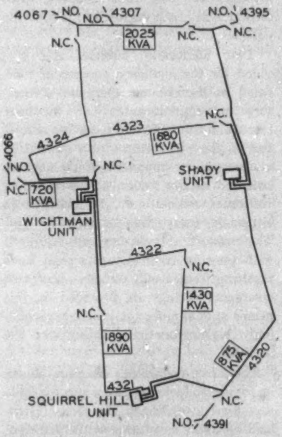

Figure 7. Squirrel Hill network: map showing network units, 4-kv mains, and connected loads

All of the faults on the distribution system have cleared without outage to other than the faulted circuit. There have been 30 faults causing circuit outages. Following 17 of these outages, the circuits were returned to service in two minutes or less.

There were two failures of station equipment at Verona, a potential transformer and a regulator, and a failure of the power transformer at Hulton, none of which caused any load to be dropped.

Analysis of the foregoing data indicates that there has been no load dropped as a result of inherent conditions of the network. The conditions causing total network outage would have resulted in distribution interruption if the circuits had been radial. As shown by the single-line diagram in Figure 2, the subtransmission circuits supplying the Verona-Oakmont network units all connect to the Verona bus. A network designed to have its transmission sources come from several transmission or switching stations, instead of all being connected to one bus, would be less subject to the condition of all circuits being deenergized at one time, although circulating currents may become a problem. Inverse reactive compensation normally corrects this tendency.

Flexibility in operation and ease of obtaining outages for maintenance and testing have been proved. Weekend outages and the planning of outages long in advance are unnecessary. While there are probably those who believe that well-planned switching procedures are acceptable at long intervals to clear station equipment without customer outages, as may be required with radial systems, most operating personnel will prefer equipment that can be removed from service almost at will, if it is otherwise economical.

The Squirrel Hill Network

This project provides overload relief for Schenley and East End substations and for 4-kv circuits originating at these substations. The area served is outlined in Figure 7, which also indicates the arrangement of 4-kv network mains, network-unit locations, and connected loads. The 22-kv transmission connections are

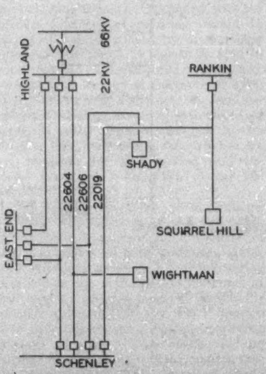

Figure 8. Squirrel Hill network: schematic diagram of 22-kv connections

shown in Figure 8; Figure 9 shows a typical network-unit diagram. The initial load being served is 7,500 kva in an area of three square miles, and the average load density is 2,500 kva per square mile. Service to this area was provided by one radial circuit from Schenley substation and two temporary 2,000-kva unit substations, which were installed to release a feeder from Schenley and another from East End substation.

The 4-kv network mains consist of overhead open-wire lines and underground cable lines. The overhead conductors are 1/0 and 4/0, and the cable sections are 350,000-circular-mil multiple-conductor cable.

For the 4-kv connections to network-unit circuit breakers, single conductor 500,000-circular-mil cable with oil-base rubber insulation, a neoprene jacket, and lead sheath will be used. This will avoid potheads in circuit-breaker cubicles where limited working space is available.

The unit-type network substation, illustrated on the location plan in Figure 10, includes a 3-position disconnecting switch for the 22-kv cable connections, a 3,750-kva transformer equipped with tap changing under load (*TCUL*), and inverse reactive compensation. The 4-kv transformer circuit breaker has network relaying for reverse current control and selective reclosing. The feeder circuit breakers connecting the network mains are relayed for overcurrent, timed reclosing, and bus differential protection, which also includes the transformer circuit breaker. The 4-kv automatic air circuit breakers are the truck-mounted withdrawal type, each enclosed in a separate cubicle.

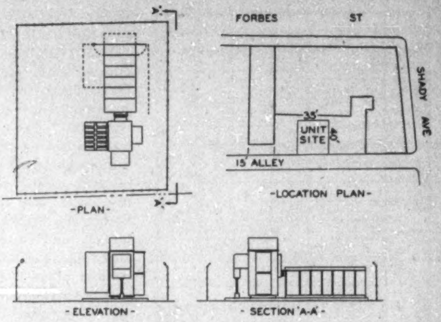

Figure 10. Squirrel Hill network: typical location plan of network-unit installation

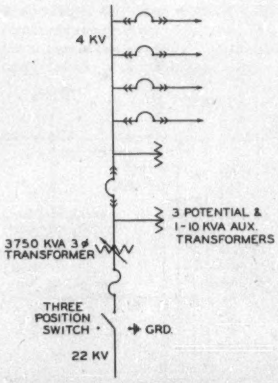

Figure 9. Squirrel Hill network: schematic diagram of a network unit

Two additional cubicles are provided for the auxiliary equipment indicated in the one-line diagram. Necessary metering includes one watthour meter and three thermal recording ammeters on the transformer; also three thermal recording ammeters which may be switched to any feeder, and a recording voltmeter which may be switched to either the transformer or the 4-kv bus. The network transformers are equipped with fans for cooling during peak loads resulting from a unit outage. Increased emergency ratings are provided by this means at minimum cost, with correspondingly higher functional ratings for the network.

The 22-kv connection diagram, shown in Figure 8, includes 22-kv subtransmission lines available in the area. Highland 66/22-kv substation is the principal source of supply for this area, with East End, Schenley and Rankin as switching stations which also serve as additional supply substations because of connections from other parts of the 66-kv system.

The Wightman, Shady, and Squirrel Hill network substations are supplied from 22-kv circuits *22,604*, *22,606*, and *22,019* respectively.

The 4-kv network diagram shows network tie mains, principal radial branches, and ties to adjacent radial circuits. These ties are part of the existing radial system and will be left in place to provide further overload relief, when required, and emergency service to portions of adjacent circuits in case of feeder faults or other emergency conditions. The connected light and power load in kilovolt-amperes is shown for each 4-kv network circuit.

New Features

The new features in the Squirrel Hill network as compared with the Verona–Oakmont network include the following items:

1. Larger and more economical size unit, that is, 3,750-kva instead of a 1,500-kva unit.
2. Regulation by means of tap changing under load in place of induction regulators. Inverse reactive compensation, however, is provided for both systems.
3. Air circuit breakers instead of oil circuit breakers for 4-kv switching.
4. Elimination of 4-kv potheads in circuit-breaker cubicles by using rubber insulated cable for connections to 4-kv circuits.
5. Factory-built unit-type equipment.
6. Alley locations for two out of three unit installations. The ground space at the third site is sufficient to accommodate the mobile-unit substation.

Advantages of Primary Networks

A comprehensive review of 4-kv radial and network systems shows the following advantages for the primary network:

1. Economical system investment is obtained by means of: single 22-kv connection per network substation; elimination of 22-kv automatic service restoration which is usually required with radial systems; the use of relatively large-size transformer units; bus regulation by means of automatic tap changing under load; the elimination of 4-kv feeders to circuit areas; and the use of factory-built unit-type equipment.

2. Reliable service is illustrated by means of an 18-year performance record of a primary network system.

3. Operating economy and convenience results from less prearranged switching for transfer of load during maintenance periods and reduced need for mobile substa-

tion unit. Two-way feed to all loads permits removal from service of any 4-kv circuit breaker or unit without interruption of service to customers. Faulted cable sections in tie mains can be isolated and service restored without extended interruption.

4. Improved voltage regulation and reduced flicker is inherent in the network system as a result of the 2-way feed to load and branches connected to the network mains.

Conditions Favoring Primary-Network Applications

While primary networks have not been used extensively on the Duquesne Light Company system, the advantages listed above warrant further consideration of this type of system for other areas. It is interesting to note, therefore, some of the conditions that favor the installation of such a system:

1. High rate of load growth.
2. Substantial overload relief requirements.
3. Areas of reasonably uniform load density with sufficient total load to warrant three or more network units. Scattered high-density areas with intervening parks, rivers, lakes, or undeveloped sections are not in general adaptable to network service.
4. Expanding urban areas that are in need of a flexible distribution system and a high degree of reliable service.
5. Areas supplied by comparatively long 4-kv feeders. When overload relief is required, a network installation can release such long feeders to serve load close to substations where feeders originate, and to share load of other feeders also in need of overload relief.

In areas where future primary networks are contemplated, the initial unit installation may be arranged for radial operation of 4-kv circuits. At such time that additional units are needed for further overload relief or voltage improvement, the primary network system can be established.

It should be noted, however, that certain radial systems, which are supplied by substation units that do not require duplicate transmission connections with automatic service-restoring features, may be lower in cost than network installations.

In urban areas, on the other hand, where it has been customary to provide radial service from 2-bank tie circuit-breaker substations, or 1-, 2-, and 3-bank automatic loop substations, as well as other similar types for a high degree of reliable service, the primary network will be preferable on a cost basis and also will provide important operating advantages.

Discussion

Leonard M. Olmsted (Duquesne Light Company, Pittsburgh, Pa.): Even though one primary network described in this paper has been in service approximately 18 years, the system must still be regarded as new when compared with other methods of distributing electric power. New methods usually have new problems, and it is my intention to discuss some of these new problems here. It is necessary to keep clearly in mind certain distinct differences between network and radial distribution. Whereas the load pickup on a radial system in case of transmission or substation trouble either is manually controlled and placed where it can be carried or picked up automatically on the original distribution feeder at the substation, the load on a network system is picked up instantaneously by redistribution among the remaining sources of power. This redistribution in the network may be totally different from the normal distribution of load, and is governed solely by the characteristics of the various components. This means that any tie circuit between network units may be required at any time to operate supplied from one end only with emergency loading 200 per cent or more of the normal load. Under such conditions, the safe rating of the entire system may well be limited not by the units themselves, or even by the normal ratings of the circuits, but by the emergency ratings of the tie circuits between the units. It is not likely that such an emergency condition will be detected in the field with the metering equipment usually provided, and it is essential, therefore, that it be predetermined either by staged field tests or by calculating board analyses.

Another consideration worthy of note is the effect of network operation upon the clearing of faults. On radial circuits it is becoming recognized that the circuit breakers cannot be expected to protect the smaller sizes of overhead wire. There has been continual compromise between the desire for increased sensitivity and extended reach of the protective equipment, and the requirements for adequate co-ordination with circuit fuses and other protective devices.

On networks, it becomes necessary to clear a fault at two circuit breakers, each with a setting substantially similar to those used on a radial circuit; the resulting level of protection may well cause an increase in the extent of damage caused by faults on the open wire plant.

It has been the practice to install cutouts on radial circuits with interrupting capacity suitable for the duty which can be encountered on the radial circuit. On primary networks, particularly those with larger units, the interrupting duty may be increased substantially, which may cause less satisfactory performance of the fused cutouts on the distribution transformers.

Several of the papers presented here have shown little or no primary circuit switching in or between network mains, or to adjacent radial circuits. It is our opinion that this switching should be eliminated, with the definite objective of reducing hazard to personnel and equipment by discouraging improper switching. It should be kept in mind that the load connected to a primary network may well be on the order of 5,000 to 10,000 kva and, if the network were de-energized, closing one set of switches to an energized radial circuit would pick up this block of load. Obviously the switches are not adequate for this service, and the result would be undesirable, to say the least.

The original literature about primary networks was based upon units generally of 1,500-kva capacity, and a number of networks with such units have been giving very satisfactory service. It is interesting to note that all of the papers presented at this meeting describe larger units, on the order of 3,000 to 4,000 kva, which appears to be a distinct change in the thinking about primary networks. This change in size appears desirable, and it is my opinion that the systems now being installed should render good service to distribution customers for a long time.

Figure 1. Schematic diagram of Bloomfield network

D. E. Nesbit (Duquesne Light Company, Pittsburgh, Pa.): As a result of the successful use of the 4-kv primary network type of distribution system in the Pittsburgh area, it is proposed to install a modified type of primary network application on the Duquesne Light Company system which will provide operating experience in the field of special network applications.

It is the purpose of this discussion to describe briefly the Bloomfield network which is a special network application using one 3,750-kva unit of a future 3-unit network system operated temporarily in conjunction with radial circuits from an existing substation.

This project has been authorized to provide overload relief for the Lawrence and East End Substations and 4-kv circuits originating at these substations. The initial network load to be served is 6,000 kva in an area of two square miles and the average load density is 3,000 kva per square mile. Service to this area is now provided by three radial circuits from East End Substation, and partially by a radial circuit from Lawrence Substation.

Some of the conditions which favor the installation of this special application of a primary network are:

1. A single-tap 22-kv supply will be used, thus eliminating 22-kv switching normally required for a loop connection to a radial substation, and resulting in lower first cost and minimum retirement when the customary network is established.
2. The area is one of reasonably uniform load density with a high rate of load growth sufficient to warrant the future installation of one or more additional units.
3. Operating experience will be provided with a special type of network that can be used as an intermediate step in other locations, if found satisfactory.

Figures 1 and 2 of the discussion show 22-kv transmission connections, arrangement of the 4-kv network mains, network unit location, and connected loads of the proposed network. The network area is to be served from one 3,750-kva 22/4-kv unit substation (Bloomfield) and three 4-kv circuits from East End Substation. Nine remaining 4-kv circuits from East End Substation, which serve adjacent areas, will continue to be served from that location.

The 4-kv network mains consist of overhead 1/0 and 4/0 open wire lines and 350,000-circular-mil multiple conductor underground cable lines. For the 4-kv connections to the network unit circuit breakers, single-conductor 500,000-circular-mil cables with oil base rubber insulation, neoprene jacket, and lead sheath will be used to avoid potheads in circuit breaker cubicles.

The 3,750-kva unit type network substation at Bloomfield is similar to and includes the equipment listed in the discussion of the Squirrel Hill primary network. Tap changing underload facilities with inverse reactive compensation will supply the regulation requirements for the network unit at Bloomfield while at East End Substation, three existing single-phase induction regulators reconnected for inverse reactive compensation for each network feeder will be used for this purpose. It is planned to operate the single-phase induction regulators independently of common phase control pending operational experience.

The installation of the 3,750-kva unit at Bloomfield has been completed. Cut-in for network operation is expected to follow within two months. After the load on the Bloomfield network passes 7,500 kva, a review of operating experience, rate of load growth, general area requirements, together with service reliability required for the network area will determine the best time for the installation of the second network unit.

There will be a temporary deficiency in the emergency rating of the network with a unit out of service. Manual transfer switching may be required under some conditions. After the installation of the second unit, the deficiency in automatic load capability will be corrected.

G. N. Hoffman (Duquesne Light Company, Pittsburgh, Pa.): The purpose of the board study of the Squirrel Hill Network was to determine the loads and voltages on the substations and tie circuits under normal, abnormal, and future load conditions. The network consists of three 3,750-kva 22/4-kv unit substations interconnected with five

tie circuits. The 22-kv circuits feeding the substations and their loads were set up on the a-c calculating board in addition to the 4-kv network tie circuits and loads. Readings were taken with all substations in service and with each substation out of service for present loads and for the maximum load capability of the network. The effect of inverse reactance was simulated by maintaining the same 4-kv bus voltage at the network substations. The ultimate load capability of the network and the elimination of two bottlenecks in the circuit design were the results obtained from the board study.

The present network load is approximately 7,500 kva distributed on the five tie circuits. The board readings showed this load to be well within the ratings of the substations and tie circuits with all substations in service and with any one substation out of service. The results are shown in Table I of the discussion.

In order to ascertain the ultimate load capability of the network for the present circuit and substation ratings, the 4-kv loads were increased 80 per cent and the 22-kv loads 10 per cent. The previous tests were repeated with the increased loads and in several instances the data showed substation and circuit loads in excess of emergency ratings. The test showing the maximum substation load having been set up again on the board, all 4-kv loads were reduced proportionately until the load was within the rating of the substation. This showed the load capability to be approximately 167 per cent of the initial 7,500 kva load, or approximately 12,500 kva.

Examination of the data showed cable loads exceeded cable ratings at two locations when the network was carrying 12,500 kva. Circuit 4321, Figure 7 of the paper, was carrying 3,700 kva at Wightman Substation when Squirrel Hill Substation was out of service, and circuit 4320 was carrying 4,200 kva at Squirrel Hill Substation when Shady Substation was out of service.

The loads of these two circuits were brought within their ratings by making two changes in the network circuit design. A load of 1,200 kva (167 per cent of 720 kva, west of Wightman Substation) was connected to 4322 instead of 4321, (see Figure 7) whose maximum load at Wightman Substation from all tests was 1,400 kva. This change did not require any additional material or expense, as both circuits were available for this load. In addition, 1,000 kva (167 per cent of 600 kva) was transferred from circuit 4320 to circuit 4321 whose maximum load at Squirrel Hill Substation was 2070 kva. This change involved the installation of a small amount of number 1/0 wire.

The substation and circuit loadings after these changes are shown in Table II of the discussion.

W. P. Holben: The discussion on the results of the calculating board study of the Squirrel Hill Network by G. N. Hoffman is an important and helpful contribution to the subject of Primary Networks. His brief review of the procedure, the statement of the technical problems relating to voltage and division of load for various operating conditions, the tabulated summary of results, and the adjustments in the design of the network as a result of the board analysis provide specific information on an interesting phase of the engineering work associated with primary networks. This discussion demonstrates that adequate design can be assured by the calculating board method. In fact, network design cannot be completed reliably without such an analysis.

The outline of the principal features of the Bloomfield 4,000-volt network in the discussion by D. E. Nesbit provides information that was not available when the paper was prepared. This type, which utilizes a 3,750-kva 3-circuit unit networked with three radial circuits from the existing East End Substation, was suggested by R. J. Salsbury of the Duquesne Light Company.

After a review of the Philadelphia Electric Company experience and an engineering analysis of the Bloomfield area facilities, existing loads, and operating requirements, this installation was recommended and authorized on an experimental basis. Preliminary calculations and the a-c board study indicated the need for three tie mains of approximately the same impedance, in order to avoid circuit overloading with the Bloomfield unit out of service during peak load periods. Minor circuit rearrangements provided these circuit characteristics, and proper allocation of connected load is expected to produce satisfactory operating results.

The problems relating to primary networks as outlined in the discussion by L. M. Olmsted are important considerations for the network design engineer. The problems are not new since most of them also relate to radial systems although possibly to a different degree. The reference to calculating board studies in the previous paragraphs indicates necessary consideration for emergency loading with a unit out of service. An open circuit breaker at one end of a tie main imposes the load of that main on the other end of the circuit. If the load on each tie main is kept within the emergency rating of the conductors at both ends there is no overload problem resulting from an open circuit breaker. The network load capability can be definitely established by means of proper design and the usual check by the calculating board method.

The co-ordinated relay settings for the Verona-Oakmont network have produced excellent operating results. Equally satisfactory experience is anticipated for the Squirrel Hill network. Trees and storms have produced some wire burn-downs. These were usually found on number 6 or number 3 conductors of radial branches from tie mains. The operating men have expressed the opinion that this type of fault is just as frequent on radial circuits. However remedies have been proposed and may be applied whenever the cost can be justified.

The fuse cutouts in use on radial circuits, which have since been converted to form the network, have been left in service. The interrupting duty imposed in most locations is similar to that of heavy duty radial circuits that extend only short distances from large substations. The favorable experience in these cases justifies the continued use of existing cutouts on the network until replacements are made as part of a general betterment program.

The discussion at the Swampscott meeting of sectionalizing and tie switching on primary networks indicated a divided opinion among engineers and operators relative to the hazards of operational errors. It is believed however that ties between network mains are unnecessary, and if left closed inadvertently will mean loss of relay protection. Sectionalizing facilities in the mains should be kept to a minimum in order to avoid maintenance of switches that are rarely used, especially if emergency sectionalizing can be accomplished by other satisfactory methods. The primary network does not require the support of emergency ties to adjacent radial circuits. In some cases such adjacent radial circuits however will be without adequate emergency ties, if the switching is removed. It therefore becomes a matter of weighing the risk of improper operation during an emergency as compared with the disadvantages of inadequate tie facilities, or the additional expense of establishing new ties with other radial circuits. Operating experience and success in providing satisfactory switching procedures will indicate the best choice in most cases.

It is recognized that the primary network has a few limitations and that it may be difficult to justify economically in certain locations. Unit substations to supply radial circuits can be used successfully and economically in many locations. Some of these will probably become a part of a primary network system at a later date. The primary network, however, offers outstanding advantages as outlined in the paper, and favorable operating experience will encourage use of the primary network more extensively in the future.

Design and Experience With 4-Kv Primary Network Systems in the Washington Area

W. J. LANK
FELLOW AIEE

IN THE territory served by the Potomac Electric Power Company, a large part of the area formerly served by k4-v radial stations has been converted to a primary network. This development has been in progress since 1939. Under the particular conditions encountered, it has proved to give better reliability, less congestion on poles or in conduit lines, and more flexible operation than the radial system. Although this paper does not give details of the comparison of cost, the primary network system originally was adopted to reduce the additional investment required for increased loads, and all subsequent extensions have been justified on this basis.

Description of the Types of Distribution Used

The territory served by the Potomac Electric Power Company and its subsidiary, the Braddock Light and Power Company, Incorporated, includes the Washington, D. C., metropolitan area and covers 631 square miles. The maximum 1-hour integrated demand is 449,000 kw. Approximately 91 square miles, having a peak load in 1948 of 139,000 kva, is fed by 4-kv radial feeders and stations. Average load density for this area is 1,530 kva per square mile, and the majority of the distribution is underground. An area of 512 square miles, having a peak load of 120,000 kva, or a load density of 234 kva per square mile, is fed by 4-kv primary network. The greater part of the distribution is overhead; load is uniformly distributed. The 4-kv radial stations, serving both the underground and overhead system, were established twenty to twenty-five years ago and have not been permitted to expand for the last ten years. These radial stations are located in the older urban areas that are fairly well built up, where residential and small commercial load is growing at not more than 5 per cent per year. The network area is in the outlying urban, suburban, and rural areas, where bulk of new housing is being built and where the load is growing at the rate of 25 per cent per year. Customers of 300 kva and over usually are supplied directly from 13.8-kv lines.

Development of the Primary Network System

In 1938 it was realized that a large new 4-kv substation, to provide for increased load in an overhead area remote from existing stations, or equivalent facilities, would be needed. The standards of service for the particular area would require the following:

1. Sufficient 13.8-kv feeder emergency capacity to carry the peak load with any one feeder out of service
2. Sufficient substation-transformer emergency capacity to carry the peak load with one transformer out of service
3. Provision for field switching to transfer the load on any 4-kv feeder to another feeder in case of failure between the substation and the feeding point

Studies were made of a primary network system of three stations as an alternate. Cost of this system was estimated to be 66 per cent of that for a 4-kv radial system to supply the same load. A visit by company engineers to Philadelphia, Boston, Pittsfield, and Pittsburgh utilities, early in 1939, furnished valuable information on operation and performance of primary network systems. Decision was made in favor of the network. Figure 1 shows this network as it exists in 1948. Kearney, Bunker Hill, and Dakota stations were installed initially; Ivy was added in 1946. These stations are spaced about $1^1/_2$ miles apart.

The same problem existed in the outlying areas, but the cost of feeder circuit breakers, necessary for a primary network, was considered excessive for the kilovolt-amperes per feeder. To reduce this cost, 3-shot reclosing fuses were substituted.

In an older section of the city, it was necessary to abandon a large 4-kv radial station, serving an underground area, because the land was condemned for a proposed government building. Studies showed the most economical replacement

Paper 49-180, recommended by the AIEE Transmission and Distribution Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer General Meeting, Swampscott, Mass., June 20–24, 1949. Manuscript submitted November 17, 1948; made available for printing May 3, 1949.

W. J. LANK is with the Potomac Electric Power Company, Washington, D. C.

Figure 2. Building for Kearney primary network station

to be an underground 4-kv primary network. This system was installed in 1941.

As the load on any one of the 4-kv radial stations grows to such an extent that the load approaches the maximum permissible for the transformers or feeders, either the low-voltage network is extended from the downtown area, or the primary network is extended from the outlying areas to prevent replacements or additions to the 4-kv radial stations. By this policy, the service in both areas is improved by cutting back the length of the radial feeders to a smaller area, as well as rendering an improved service in the area that is cut over to the secondary-network or primary-network stations. Since the load almost invariably grows at the most rapid rate at the extremities of the areas fed from a given radial station, it usually follows that a small network station located at the point of load growth is also the most economical solution.

Primary Network Design

Consideration of service interruptions and voltage has resulted in the adoption of a maximum of 4,500 kva miles per feeder under normal conditions. In the outlying area, stations are spaced about five miles apart and located at strategic road intersections. Using the limit of 4,500 kva miles, this permits a distributed load of 900 kva per feeder. The average station will have four feeders, each having another terminal in some other station, and approximately 1/2 of each feeder's load will be carried by each station. Therefore, the normal station peak load will be $4\times(900/2)=1{,}800$ kva. In case of the loss of high-voltage supply to one station, the load of each 4-kv feeder into this station is carried from the opposite end. Therefore, the station emergency loading would be 2,250 or 2,700 kva, depending upon whether one or two feeders actually supported the station which has been lost. Studies of load factors have shown that transformers will safely carry 50 per cent in excess of their self-cooled nameplate rating in emergencies, under winter ambient conditions, without undue loss of life. Stations of the type described usually have 2,000-kva transformers. Admittedly the above is not an exact analysis since, with the loss of high-voltage supply, some energy is transferred from one 4-kv feeder to another through the station bus. In actual planning, this fact is taken into consideration.

In suburban areas, the stations are located about three miles apart, and the feeders are loaded to 1,500 kva. This gives a normal station loading of 3,000 kva and an emergency loading of 3,750 or 4,500 kva under the conditions outlined. All new transformers purchased are 3,000-kva self-cooled and 3,900 kva with forced-air cooling. Maximum emergency loading of 5,400 kva is permitted.

Maximum 4-kv feeder loading is limited to 1,800 kva. In urban areas, the stations are placed correspondingly closer, in some cases about one mile apart, to keep within this limit and to provide sufficient station capacity for the load density.

Use of Capacitors

The 4,500 kva miles of distributed load, with 1/0 overhead line, gives approximately 2.5 per cent primary drop between the first customer and the lowest voltage point on the feeder. This is the maximum permissible normal drop on the primary to stay within the limits of customer voltage tolerated upon this system. Under emergency conditions with one end open, or for loss of one station, a maximum drop of 11 per cent is permitted.

By the use of fixed capacitors in the center of the tie, the kva miles can be raised 50 per cent without exceeding the above limitations, or the maximum permissible voltage of 102.5 per cent at the center of the line off peak. Where the load is concentrated near one end, the emergency voltage at peak time with this end open may limit the load upon the feeder. In this case, the permissible load may be increased 80 per cent by the use of capacitors located near this end. Such installations have been used extensively on this system. Fixed capacitors also are used at the extremities of long single-phase taps off network ties, to improve voltages and to reduce the man-hours and copper required for load growth, or to avoid installation of more expensive regulators. Banks of fixed and switched capacitors are installed in some outlying substations to assist the regulators in maintaining normal voltage, and to maintain the voltage at not less than 89 per cent of normal upon the loss of the 13.8-kv supply.

Indoor-Type Primary-Network Station

Figures 2 and 3 show typical station-building designs for the urban and suburban areas where zoning laws require an indoor type of station. These stations purposely are made to resemble the typical $1^1/_2$-story residence. In the Washington area, it usually is necessary to acquire residential property for the strategic location of substations. The limited industrial and commercial property is so expensive that it generally is more economical to acquire residential property and install the necessary building. In this type of installation, appearance and quietness of operation are emphasized. It has been found this policy pays dividends in public relations, which are so necessary when application is made for nonconforming use for a proposed substation site. The photographs show the typical pole-line construction adjacent to the station. In this case, the cable is routed from several terminal poles to the station as unobtrusively as possible, so as to avoid a nest of poles or equipment.

Building Plan and Equipment Layout

The building is 23 by 37 feet in plan and contains the standard 3,000/3,900-kva network-type regulating transformer. In a number of locations, older 1,000- and 2,000-kva transformers banked, together with three 50-kva induction regulators connected for plus or minus 5 per cent range, are used to obtain a normal rating of 3,000 kva or an emergency rating of 4,500 kva. Switching consists of a 100,000-kva truck-type circuit breaker

Figure 3. Building for Blair primary network station

mounted in a structural iron and Transite compartment, together with disconnects, current and potential transformers. The transformer is separated from the room containing the switchgear by a fire barrier wall. The chimney on the house is a ventilating duct for exhaust of hot air. Louvers provide air intake.

Figure 4 shows a typical schematic control diagram. The transformer secondary will trip on instantaneous reverse current or over-or-under voltage on a potential transformer connected from one phase to ground on the high-voltage side. This later protection is necessary because the high-tension feeder is grounded only at the source end, and the line might remain energized from the delta side of the substation transformer on a single phase-to-ground fault. In case the transformer clears by overcurrent, indicating a fault which cannot be cleared by the feeder circuit breakers, all circuit breakers are tripped and locked open. The transformer circuit-breaker reclosing is initiated either by a network-type or by a phase-rotation and voltage-checking relay. Negative reactance compensation is used for control of voltage at all network stations.

Figure 5. Outdoor primary network station with reclosing fuses

Outdoor Type of Station

Figure 5 shows a typical outdoor network station of the type usually located in the outlying areas. Wherever zoning permits, the outdoor design is employed, consisting of the 2,000-kva transformer, induction regulator, and an automatic oil circuit breaker for transformer secondary located in cubicles. The 13.8-kv side of the transformer is protected by primary fuses. The 4-kv feeder protection consists of 100- or 200-ampere reclosing fuses. These are mounted, as part of the station, on a steel structure, but with wood cross arms to prevent flashover to ground. Each feeder position occupies 10 feet of space, so that a structure 20 by 10 feet may contain five feeders. Fuses may be replaced from the ground to avoid climbing of poles. A gunpowder-type link is used to obtain effective clearing on light faults.

Experience with the reclosing fuse for this type of primary-network service is satisfactory. The advantages of using the reclosing fuse are the low first cost and the fact that a fuse will blow only on the particular phase affected and can always be depended to blow to clear the fault. The reclosing fuse may at times fail to reclose, but this has never caused an interruption to the network service since the fuse at the other end reclosed if the fault was temporary or all three fuses were blown for a permanent fault. These fuses, in a 200-ampere holder, are rated 4,000 amperes interrupting capacity, which is sufficient for a 2,000-kva transformer station. In one station where the transformer capacity is 4,000 kva, a heavy-duty borax reclosing fuse, rated 12,000-ampere interrupting capacity, has been used with equally good results.

Disadvantages of Large Radial Stations

Figure 6 shows typical pole-line congestion which may exist in the vicinity of large radial substations. This condition results when there are only one or two clear routes from a given station and lines cannot be rerouted because there are no through streets or the streets are blocked by trees. Such congestion causes difficulty in maintaining safe working conditions, unsightliness, and a reduced security of supply to the customer. For example, a pole knocked down, lightning, or a tree falling on the wires results in a serious outage to a large area. Requests are made by civic organizations for such lines to be placed underground, and, in some cases, this has been necessary. The cost of such underground construction is difficult to support, since there is no corresponding increase in revenue.

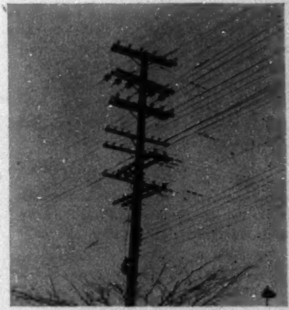

Figure 6. Congested pole line near a large 4-kv radial station

Studies of this situation have shown that, in some cases, it is more economical to break up larger radial stations into three or four network stations spaced at strategic centers and thereby avoid the more expensive underground construction Figure 7 shows the resulting pole line.

During the past year, because of certain highway improvements, there was considerable demand for underground construction through an entire community. By relocating a portion of the older radial station into a new network station and by

Figure 7. Typical pole line of a primary network system

Note the cable riser

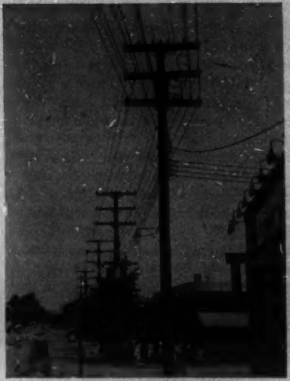

Figure 8. The main street of Silver Spring before rearrangement

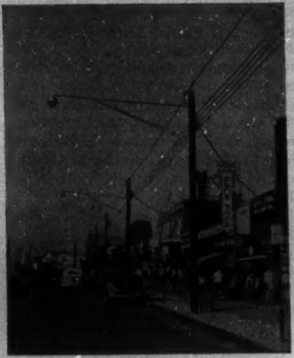

Figure 9. Improvement in the main street of Silver Spring as a result of distribution rearrangement

partial conversion to underground, partial disposal of lines and retaining poles for street lights, traffic signals, overhead secondary mains and services, it was possible to accomplish the desired improvement for $250,000. Complete underground construction would have cost $500,000. Figures 8 and 9 show this area before and after the changes.

Existing large radial stations contain from 30 to 60 feeder regulators which are a potential fire hazard. Several cases of major service interruptions experienced by other companies show this hazard must be given consideration. In a new station supplying an underground area, this hazard can be eliminated by using tap changing under load transformers, with some sacrifice in control of customer voltages. In any event, large concentrations of power give more opportunity for the spread of trouble to cause a major interruption to a large area.

In all of the large radial stations, it is necessary to operate with only one 4,000-kva transformer per bus section and with bus ties open. This type of operation is necessary to reduce the circuit breaker interrupting duty and voltage-regulator short-circuit current duty to approximately 8,000 amperes. Even this reduction is beyond the 5,000-ampere rating of a 50-kva regulator connected for 10 per cent voltage boost.

Sometimes difficulty is experienced in balancing loads between transformers. Short-time interruptions have occurred as a result of tripping transformer circuit breakers either because of trouble or accidentally.

Operating Experience—Stations

On April 17, 1948, a cable connection to a bus selector disconnect failed in one of our older radial stations. The resultant fire, smoke, and copper dust caused a flashover on insulators of both bus connections. Transformer circuit breakers supplying both busses tripped automatically, interrupting 4-kv radial service to the entire Chevy Chase, Md., area for several hours. It was necessary to await clearance of the smoke, determine the extent of the damage, and make emergency repairs before restoring the busses and radial feeders to service.

A network type of station had been built to relieve this radial station and four ties were established to one bus in this station. When the transformer circuit breaker tripped, it automatically opened and locked out the network-tie circuit breakers at this end, thereby permitting the entire network feeder load to be supplied from the other station. All of the radial feeder load was dropped when the radial bus was de-energized. This type of fault is rare, but when it does occur a considerable area is affected.

On September 7, 1948, a primary network cable failed in the Southeast–Southwest underground area. The circuit breaker connected to this cable at the near station failed to open after reclosing, due to a defective mechanism. This caused melting of contacts and subsequent arcover of the circuit breaker. The resulting fault was cleared by the transformer overcurrent relays, which tripped and locked all operable circuit breakers at this

Table I. Comparison of Operating Performance

4-Kv Radial Versus Network Feeders

Location	Years	Miles	Number of Tripouts	Number of Interruptions	Per Mile-Year Tripouts	Per Mile-Year Interruptions
OVERHEAD AREA						
Radial: Tenleytown	1.	11.6	13	3	1.1	0.26
Network: Tenleytown–Wesley	1.0	8.9	5	3	0.56	0.34
Radial: Brightwood–Brooklyn	3.0	29.4	75	30	0.85	0.34
Network: Brooklyn	3.0	12.4	11	7	0.29	0.19
Radial: Riverdale	3.0	25.7	95	41	1.23	0.53
Network: Riverdale–Sunnyside	3.0	15.8	0	2	0	0.04
Radial: Anacostia	3.0	4.7	9	0	0.64	0
Network: Anacostia–Hillcrest	3.0	10.6	13	4	0.40	0.13
Average: Radial Overhead	3.0	71.4	218	80	1.02	0.37
Average: Network Overhead	3.0	47.6	39	22	0.27	0.15
Advantage Factor Favoring Overhead Network					3.8	2.4
UNDERGROUND AREA						
Radial: Eastern	3.0	18.6	12	31	0.21	0.55
Network: Southeast–Southwest	3.0	23.2	11	6	0.16	0.09
Advantage Factor Favoring Underground Network					1.3	6.1

station. The circuit breaker connected to the opposite end of the faulty cable at the other station cleared properly. Aside from the feeder in trouble, no other service was affected, since the other network feeders continued to carry their load. In this case, a sectionalizing circuit breaker was opened in the manhole, and, except for one or two transformer banks, service was promptly restored to the balance of this faulted feeder.

It is quite evident from the two cases cited, as well as others, that the network-type station has a decided advantage over the radial type, since an entire network station may be lost without affecting service.

Operating Experience—Feeders

It is difficult to make an exact comparison of service reliability between the primary network system and the radial-type system, since the primary network is located in the outlying area that has more exposure to lightning, high-speed traffic, tree conditions, and so forth. To reduce the effect of these variables, several different radial areas have been compared with primary-network areas of similar characteristics. Results are given in Table I. This summary averages 71 miles of radial feeders against 47 miles of network feeders for the past three years. This comparison tends to favor the radial type of system, since there is usually more mileage of radial feeder exposure to cover a given area than would be required if converted to the network. The table shows that momentary faults per mile of overhead radial system for a three year period averaged 1.02 and, for network system, averaged 0.27—an advantage factor of 3.8 favoring the network. Permanent faults on the radial system averaged 0.37 per mile and the network, 0.15, or an advantage factor favoring the network type of 2.4. It is interesting to note that, in the underground system, the primary network has an advantage factor of 6.1. This improvement is probably due to use of newer single-conductor paper-leaded cable, lighter normal loading of the network cable, and less heating, due to the absence of congestion of cables in underground conduit system.

It is reasonable to expect some improvement in service for the overhead type of primary network, as compared to the radial system. The reduced congestion, already explained, results in wider spacing of wires, reducing outages due to tree limbs and wires whipping together. The elimination of parallel mains and reduced spacing between stations decreases the total wire miles. There are a minimum of supply or distribution circuits on the same pole line.

Summary

The 10 years of experience with the primary network upon the Potomac Electric Power Company system serving the metropolitan area of Washington, D. C., have resulted in the following conclusions:

1. A primary network system can be installed at a lower cost than new large radial 4-kv stations where load distribution is uniform and reserve facilities against loss of equipment would be supplied for the radial system.
2. Construction to supply new loads is simpler and more flexible with the primary network system, since it tends to avoid overhead wire congestion and the need for underground construction.
3. Operating reliability is improved.
4. Voltage regulation is improved.

Since the start of the war period, the primary network system has grown from 25,000 to 106,000 kva. It was able to pick up large loads with only small increments of new materials during this period, and expected investment economies have been realized.

Discussion

V. A. Rydbeck (General Electric Company, Schenectady, N. Y.): The author's experience with the primary network system confirms our thoughts on its flexibility, reliability, and economics. Its comparative operating performance is particularly impressive.

With reference to his adoption of a maximum of 4,500 kva miles per feeder, this should be a helpful practice in planning the number and location of substations. With a given conductor size, system power factor, and load arrangement, voltage drop is in direct proportion to the product of load times distance. For a given voltage drop, the feeder length can be increased as load is decreased and conversely. A 2.5 per cent primary drop between the first customer and the lowest voltage point on the tie feeder agrees with our thinking of good design practice for providing satisfactory voltage.

The application of shunt capacitors to primary networks, so far as is known, has not been widely practiced. When these capacitors are connected at the mid-point of the respective tie feeders, then a maximum amount of normal voltage improvement is achieved. The 50 per cent improvement in voltage brought about by these capacitors means that primary networks may prove practical in areas of light load density or that existing networks which have excessive voltage drop may be improved at moderate cost.

A capacitor bank connected at the midpoint of a network tie feeder would normally draw one-half of its leading current from each end of the tie feeder. In time of emergency with the transformer at one end of the tie feeder out of service, the leading current of the capacitor would all be supplied from the end in service and hence the voltage improvement effected by the capacitor is doubled. The ability of the capacitor to improve voltage during times of emergency should prove helpful in many cases as a means of deferring additional system investment to take care of emergency conditions.

G. B. Dodds and **R. S. Smithley** (Duquesne Light Company, Pittsburgh, Pa): In Table I of the paper is given a comparison of operating performance of several 4-kv radial areas versus primary network areas. There are several points in connection with the table that are not clear.

1. In the paragraph dealing with operating experience it states that the momentary faults per mile of overhead radial system for a 3-year period averaged 1.02 and for the network system averaged 0.27 which the author claimed is an advantage factor of 3.8 favoring the network. It is not clear that the figures indicate an advantage in favor of the network since it is usually assumed that the greater the percentage of temporary faults, the better the continuity of service provided. On this basis it would appear that the radial system had 1.02/1.39 or 73.37 per cent temporary faults while the network system had 0.27/0.42 or 64.37 per cent temporary faults. This is an advantage factor of 73.3/64.3 or 1.14 in favor of the radial system.

It may be that our understanding of the figures on the table are not correct and if this is so we would appreciate further explanation of the figures.

2. It would be of interest to know whether the columns dealing with number of interruptions (which we interpret as permanent faults) in Table I apply only to faults causing circuit breaker tripouts or whether partial circuit interruptions also are included.

It also would be of interest to have a comparison for the two systems, of the current pick-up of relays on the circuits, the time setting of the relays, as well as information concerning size of conductors, whether bare or covered, and so forth.

It was mentioned in a recent paper by Bryce Brady[1] that somewhat better service continuity might be expected on radial circuits which have co-ordinated sectionalizing fuses, reclosers, and circuit breakers than on primary networks where this coordination does not seem possible. The discussers agree with this feeling.

The discussers recently made studies of the time required to clear faults on primary network feeders as compared to times for radial feeders in which the radial feeders were equipped with instantaneous relays for the first tripout, these instantaneous relays being cutout on recloser. The use of instantaneous low set relays on primary network feeders does not seem to be practical because of overreaching and tripping out for faults on other feeders.

Table I of the discussion shows that on the radial circuit all faults above 850 amperes will cause relay operation in two cycles or less, while on the network feeders sequential operation of the circuit breakers at the two ends often occurs and total relay times are as high as 1.3 seconds at 10,000 amperes. For lower values of current, times will probably be longer. The longer time required to clear faults on network systems will result in a greater percentage of faults becoming permanent. The higher values of fault currents also will increase damage.

The discussers agree that there may be advantages in economics and in operation in favor of primary networks, but they also feel it desirable to recognize the disadvantages of higher fault currents and longer clearing times of faults that usually result from network operation.

Table I. Comparison of Operating Time of Relays on a 4-kv Primary Network Versus 4-kv Radial Circuits

	Network Circuits	Radial Circuits	
	Time Delay	Time Delay	Instantaneous
Relay pick-up in primary amperes	560	480	560
Time	0.4 second at 1,000% of pick up	0.15 second at 1,000%	

	Fault Current				
Condition	Total	Each Relay	Relay Time	Fault Current	Relay Time
Fault at center of circuit	10,000*	5,000	0.43 second	**	1 to 3 cycles at all currents above 850 amperes

		Total Time for Both Relays Operating Sequentially
Fault at end of circuit	10,000 amperes	1.3 second

The above times for the network will increase as fault currents decrease.

* The 10,000-ampere fault current is based on 3—3,750-kva unit substations connected in a 4-kv network.

** Maximum fault current from a 2,000-kva unit substation is 3,000 amperes at 4 kv.

REFERENCE

1. IMPROVEMENTS TO OKLAHOMA CITY PRIMARY NETWORK, Bryce Brady. *AIEE Transactions*, Part I, volume 68, 1949, pages 701–03.

W. J. Lank: Mr. Rydbeck has concisely expressed the argument for capacitors upon primary network ties. One additional use of capacitors is to hold up the voltage on a lateral near the center of a long tie feeder. As Mr. Rydbeck says, the capacitors have been particularly useful in holding up voltage under emergency conditions.

Mr. Dodds and Mr. Smithley have raised the point that the ratio of temporary to permanent faults is slightly better for the radial system than for the network system. Part of this may be due to the more congested pole lines causing more tree limbs to get across lines with the radial system. So far as is possible, the areas compared have about the same exposure and tree conditions. The ratios given in the paper compare the number of "trip-outs" per mile year and the number of "interruptions" per mile year of the radial with the primary network feeders. Under the conditions existing, it is believed that this is a much better indication of the reliability than the ratio of temporary to permanent faults used by them.

By a "tripout" is meant an operation of the circuit breaker or fuse, followed by successful reclosure and restoration of load along the main feeder up to branch line fuses. In the case of a primary network feeder, simultaneous operations at both ends are treated as one tripout. If a circuit reclosed successfully and supplied the major part of the load, but part of the main line had burned clear, it was treated as an interruption.

They have raised some questions about current and time settings and details of construction. The current settings are usually from 240 to 480 amperes, depending upon the load and length of the feeder. Time is usually 20 cycles for the circuit breaker contacts to part at 600 per cent of minimum trip current. In some cases, instantaneous trip attachments set for approximately twice the fault current at the opposite end of the primary network feeder are used in addition to the time delay relays to assist co-ordination. All new construction uses bare wire but most of the older lines have weatherproof wire.

The author agrees with the statement that careful sectionalizing, co-ordinating fuses, and strategic location of reclosers will do much to improve service. The only difficulty found in this respect with the primary network is that it is not practical to use an instantaneous trip at the substation to protect branch line fuses. If service to the branch line is of sufficient importance, the fuses may be omitted if the frequency of trouble is low or a recloser or reclosing fuses used if it is high.

On bare copper wire comparatively few faults become permanent unless confined to a given location by a cause such as a tree limb. Many staged tests using fine wire to initiate the fault have not burned down a circuit. In the case of the comparatively slow blowing reclosing fuses used in some locations, there probably is a slight increase in the percentage of permanent faults, due to the long clearing time of the fuses. Experience cited in Table I of the paper shows that this is more than over-balanced by the reduced number of faults.

In the example of relay settings given by Mr. Dodds and Mr. Smithley, they use a greater time delay for a network feeder. If the relay time delay is sufficient to co-ordinate with the large branch line fuses which are required in order not to blow on the first instantaneous trip on a radial feeder, it will be sufficient for proper selection on a network feeder. The network does lose the advantage of a first instantaneous trip to protect the fuse, as discussed before.

To summarize, we feel the final criterion of reliability is service to the customer, which we have found to be better with network operation.

Reduction of Interference from Radio-Frequency Heating Equipment

G. W. KLINGAMAN
ASSOCIATE AIEE

AS A RESULT of regulations adopted recently by the Federal Communications Commission which govern radiation from radio-frequency heating equipment,[1] there has arisen a need for information on practical methods of dealing with this problem. Since it occurs in a relatively new field of application for electric power, industrial users may find themselves unfamiliar with the necessary techniques for dealing with it. In order to make such information available to industry, committees of the AIEE and the Institute of Radio Engineers have undertaken an investigation of good engineering practices which will minimize or reduce radiation from radio-frequency heating equipment. It is the purpose of this paper to summarize recommended procedures which have been developed through the work of The Committee to Formulate Procedures of Good Engineering Practices in Instances Where Interference is Encountered (sponsored by the AIEE), The Industrial Electronics Committee (sponsored by the Institute of Radio Engineers), and the Engineering Committee of the Induction and Dielectric Heating Section (sponsored by the National Electrical Manufacturers' Association).

The Need for Shielding

High-frequency electric power sometimes appears to behave quite differently from the familiar 60-cycle version. Actually, there is no fundamental difference. The difficulty lies only in the fact that effects which were negligible at 60 cycles become very important as the frequency is raised. It becomes increasingly harder to confine electric currents to desired circuits. Dangerous potentials may exist between apparatus cases which can cause burns to operators. High-frequency currents may circulate in control devices and make them inoperative, or otherwise impair their functions. Circuits and apparatus, which are not associated with the equipment in any way, may pick up high-frequency currents. The ability of high-frequency power to propagate itself through free space without conventional guides, such as wires, leads to interference with apparatus at great distances. The energy may travel along the earth's surface, or it may be reflected from the ionosphere to be returned to earth at tremendous distances from its source. On the other hand, it may be conducted on wires directly to the remote point. The solution to all such hazards is the use of adequate shielding about the high-frequency apparatus, to confine the currents to safe channels.

The Nature of Radiation

The oldest type of generating equipment is the rotating machine. However, this device is not generally used above 10 kc per second. In the range 10 kc per second to 500 kc per second, a common power source is the spark gap. Interference from spark equipment is distributed over a very wide frequency range. For example, a 20-kc per second generator will radiate a continuous spectrum of noise, very similar to automobile ignition interference, which may extend well into the very-high-frequency regions. Vacuum-tube oscillators are used extensively between 200 kc per second and 200 megacycles per second. The frequency spectrum of such generators consists of a fundamental and other frequencies which may be detected with varying amounts of intensity up to and beyond the 300th harmonics.

Essentially, the generation of frequencies other than the fundamental is a result of wave-form and modulation effects. These produce frequencies which are harmonics, plus sideband frequencies which bear no harmonic relation to the fundamental. At times, such phenomena as moding and parasites cause trouble. Moding is manifested as a sudden frequency shift or "skip" of the generator during the loading procedure. Parasites are spurious frequencies generated in a path other than the normal oscillator circuit in the generator. Moding, on the other hand, is a normal oscillator characteristic which is present when a tuned load is tightly coupled to the tank (coil–capacitor) circuit in the generator.

It has been pointed out that high-frequency energy leaks readily into stray paths, where it may produce undesirable local and remote effects unless it is confined to proper circuits. High-frequency electric currents cause radiation when they flow along unshielded conductors having dimensions which are an appreciable fraction of the wave length of the current. The total power loss by radiation from a conductor can be represented at any selected point along its length as the product of an effective radiation resistance and the square of the current at that point. The total impedance measured at the point contains additional components, due to the self-resistance and reactance of the conductor. It often is possible to calculate the effective impedance such a stray path will offer to a radio-frequency voltage source and to reduce it to a simple electric circuit.

An alternative to this "circuit concept" is the "wave concept," which pictures the flow of electric energy in terms of electric and magnetic fields. This view is more fundamental, but more difficult to visual-

Figure 3. Design data for a sensitive high-frequency current probe

ize and more complicated mathematically.

Frame currents along the edges and over the surfaces of metallic enclosures surrounding the apparatus are serious sources of radiation. For example, in Figure 1 the necessity for shielding has been recognized by the designer, but due to faulty construction, the shielding is far from perfect. At the applicator, the shielding has been made of large-mesh iron screen, having a high surface reactance and a high resistance because of the characteristics of the iron. This produces excessive leakage of the radio-frequency flux from the inside face of the screen to the outside faces, and results in current I_1 and I_2. A large opening to admit a conveyor belt gives rise to current I_3 around the periphery of the opening. The thickness and conductivity of the generator shield are adequate, but poor contact around the door causes current I_6. Similarly, a slit in the side panel results in an external current I_7. Some additional leaks might be poorly screened windows, open floors, and poor joints around panels.

Currents on power and control wires occur in two ways. Figure 2(A) shows a transverse (wire-to-wire) current wave. Figure 2(B) shows a longitudinal (wire-to-ground) wave. Both waves are transmitted on the inside of a shielding conduit, from the installation to a point where the wires may be exposed to free space and cause radiation. The magnitude of radiation per ampere is apt to be much greater for longitudinal current than for transverse current. On the other hand, currents such as I_4, I_5, I_8, and I_{11} in Figure 1 may be induced on the outside of power conduits due to shielding leaks. A similar current I_9 can occur on the outside of pipes connected to the unit for supplying water, gas, or air to the installation.

A common fallacy is the belief that connecting the apparatus to ground is a convenient cure for high-frequency troubles. Some installers have gone to great pains only to discover that no improvement has been obtained. Such a connection with current I_{10} is shown. It usually has considerable radiation resistance and may actually increase interference instead of reducing it.

Finally, an installation that initially may have been satisfactory eventually may start to leak high-frequency power. Factors contributing to this condition are corrosion of metal parts and carelessness on the part of the operators. A poor choice of metals, from an electrochemical standpoint, may weaken a joint or contact in time.

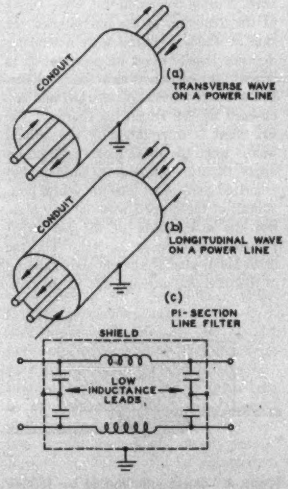

Figure 2. Stray currents on a power line and a filter for eliminating them

The various paths in Figure 1 may be reduced to simple electric circuits as previously discussed. Voltages are induced across the equivalent impedances by direct conduction, by capacity coupling (for example, stray capacities C_1 and C_2), by inductive coupling, or by direct radiation. One such voltage is E_1 between the generator and applicator, due to the impedance of various current paths between them. In the case of spark generators, the complex form of such interference may shock-excite a number of paths at their resonant lengths. This may result in radiation peaks at certain frequencies which are higher than the general level of interference.

Once the high-frequency energy leaves its conventional circuits, it enters free space, where it continues to travel outward by a sort of self-propagation. In this medium, the wave concept is useful. It is found that the electromagnetic field has two components—an induction field which attenuates very rapidly (within one or two wave lengths), to leave only a radiation field which continues to great distances, depending on its intensity. The radiation field may further be separated into a ground wave, which follows the surface of the earth, and a sky wave which is reflected from the ionosphere. The ground wave is greatly affected by the conductivity and dielectric properties of the earth and attenuates rather rapidly. The sky wave attenuates only slowly.

The multiplicity of radiation sources in Figure 1 are found to have different relative phases at the various points in space, in such a way that at certain points they tend to add, and at other nearby points they tend to subtract. Reflections from metallic objects or electrical discontinuities in the neighborhood will produce similar effects. This gives rise to pronounced "interference patterns" or "standing wave patterns," that is, up and down variations of the field strength over relatively short distances.

The ability of a conductor to radiate energy from its surface increases with increasing frequency, up to a certain point. This is entirely due to its increasing electrical length (length in terms of a fraction of the wave length of the current it carries), and its increasing electrical spacing from a ground or other reflecting plane. At frequencies used for induction heating, electrical lengths are short and radiation is not a serious problem. Design practices which would be intolerable at dielectric heating frequencies may cause little trouble at lower frequencies. However, the possibility of harmonic or spark interference makes such practices questionable, in general. At lower frequencies, the conduction of currents along power lines is a considerable source of interference at a distance from the equipment.

LOCATION AND MEASUREMENT OF RADIATION

The rules adopted by the FCC are given in Part 18, a copy of which may be obtained from the United States Government Printing Office.[1] The measurements made to determine whether the limits for industrial heating equipment are met consist essentially of first obtaining a polar plot of the field intensity at 1,000 feet, for example, around the equipment. Following this, readings are taken along a radial in the direction of the strongest lobe of radiation, as determined from the polar plot, to determine the maximum intensity at one mile. The strongest field reading at that distance (antenna vertical or horizontal), at a height of 12 feet, will show whether the limit of 10 microvolts per meter at one mile specified in the rules is complied with. The rules should be referred to for the detailed measurements in any particular case. This limitation applies to all fundamental, harmonic, and spurious emissions. Radiation from a power line must be less than 10 microvolts per meter, one mile from the equipment and 50 feet from the line.

Various devices have been designed to assist in the measurement and location of high-frequency radiation. Chief among these are field intensity meters, which are merely refined and calibrated receivers. Below 18 megacycles, the FCC specifies that such meters shall employ loop antennas. Above 18 megacycles, the specified antenna is a doublet (rod), mounted on an appropriate support. Data taken with such meters at close spacings (within one wave length) should recognize the presence of a strong induction field. The weakest field that may be explored with a field intensity meter is determined by the natural noise level in the vicinity of the meter. Such noise tends to mask the signal and give erroneous readings. Additional instruments for identifying the frequencies of interfering sources, locating leaks in shields, and so forth, include interference locators, radio-noise meters with rod antenna, a loop probe, and others. A very simple type of current probe, using shielded inductive coupling to the circuit is shown in Figure 3.

FCC regulations are concerned with the radiated field. Stray energy also may travel along metallic paths (wires, and so forth) to a remote point where it may cause interference with the operation of other apparatus. This is known as conducted interference. FCC regulations recognize conducted interference indirectly by specifying radiation field measurements along power lines at one mile distance.

When the height above ground of the receiving antenna and of the radiating wires is small compared to a wave length at the frequency of the interference, the rate at which a ground wave attenuates depends largely upon its polarization in space. The earth acts as a "lossy" dielectric which is alternately charged and discharged by the advancing energy. The net effect is attenuation of the ground wave; when the above height restrictions apply, the attenuation of the horizontally-polarized component (electric vector horizontal) of the ground wave is very high, but the attenuation of the vertically-polarized component is less. On the other hand, when the height above ground of the receiving antenna and of the radiating wires is large compared to a wave length at the frequency of interference, the received field component controlled by the losses in the earth becomes relatively unimportant compared to the resultant of direct and ground-reflected waves, and the difference in attenuation of horizontally and vertically polarized components becomes small.

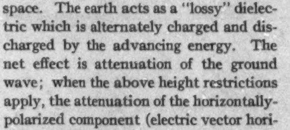

Figure 4. Shield joint formed by locking two metal sheets and attaching them to the supporting frame

REMEDIAL METHODS

The electromagnetic wave in free space attenuates inversely as the distance from the source. Hence, physical isolation from any receiving point is one method of attenuation. In most cases, it is not practical.

When electric apparatus radiates interference over a wide range of frequencies due to the nature of its construction, it may be modified to reduce its bandwidth in some instances. An example of this would be the replacement of spark generators with tube equipment. Another example would be the substitution of a filtered d-c supply in self-rectified vacuum-tube generators.

A third principle of suppression is to cancel approximately one field with another of equal amplitude and opposite phase. This is what occurs when a current-carrying conductor is brought close to a parallel nodal plane (reflecting surface). Similarly, when a conductor carrying an equal and opposite return current is brought close to the transmitting conductor, approximate cancellation takes place. Open-wire transmission lines use this principle. The radiation efficiency of a closed loop may be reduced, in general, by reducing the enclosed area or volume. As another example, the balanced operation of a tuned circuit may, in some instances, reduce its effect on other circuits by cancellation.

An effective and recommended method of reducing radiation is by means of reflection. One very efficient reflector is a shield, made of a good conductor, about the radiation source. The lower the surface resistance and reactance of such a shield, the more efficient it becomes as a reflector. Such shields form a nodal surface which completely surrounds the high-frequency circuit. Single shields often produce sufficiently satisfactory attenuation to meet FCC regulations. A second shield, surrounding the first and insulated from it, gives approximately twice the attenuation (in decibels) of a single shield. When the shields are placed in parallel by a systematic short-circuiting device such as cell-type construction, the attenuation is somewhat reduced but still higher than for a single shield. Attenuation may be impaired by slits, poor joints, excessive flux leakage due to the use of iron wire, too large a mesh of screen, high shield currents due to undue proximity of internal circuits, too small a shield size, or unscreened openings of one sort or another.

As pointed out previously, an attempt often is made to use the earth as an equipotential plane, by connecting each piece of apparatus to a good earth ground (multiple grounding). At best, this yields only mediocre results, since, in practice, it generally is impossible to place apparatus cases at true ground potential because of ground bus and shield impedances.

Nodal (reflection) points in wire conductors may be obtained by line filters or shielded transformers. Figure 2(C) shows a low-pass π-section filter, which is effective against the transmission of both longitudinal and transverse current waves.

It is desirable to choose the image impedance of such a filter as low as possible. The cut-off frequency should be well below the lowest frequency present in the generator output. Low-loss impedances should be used. Additional precautions, to insure high attenuation at fundamental and harmonic frequencies, include low capacitor inductance, low ground-wire impedances, low capacity between input and output terminals, shielded assembly, and mounting of the filter shield directly on the wall of the main apparatus shield, at the point where the filtered wires leave the main shield. Such line filters generally are used in wire circuits which eventually reach open space where they can radiate energy. In place of a line filter, it often is possible to insert a transformer with a grounded electrostatic shield between primary and secondary, in series with a wire circuit. The ground return from this shield should have negligible impedance.

A considerable amount of attenuation may be introduced by surrounding an interference source with an absorbing material.

Iron, with its high resistance, is fairly effective for this purpose. A laminated shield consisting of sheet steel with a copper plating impedes the progress of a radio wave in two ways:

1. The copper surface reflects electric energy.
2. The steel core attenuates by absorption any energy which may penetrate the copper barrier.

However, if possible, the copper coating should be thicker than the depth of current penetration, so that power losses in the underlying steel will not be excessive.

Good Engineering Practice

DESIGN OF EQUIPMENT

First choice of frequency for dielectric heating and some induction heating processes should be the assigned FCC bands. Among the channels to be avoided in all cases are those assigned to distress, navigation, and domestic sound and television broadcasting. The possibility of harmonics, sidebands, or spark noise occurring in these bands should be considered particularly. Well-known engineering practices should be followed to avoid harmonics, parasites and moding. Reduction of the bandwidth through the use of filtered d-c plate supplies with tube equipment is advocated. The wave form of the generated frequency should be as undistorted as is consistent with economical design. In the case of spark equipment, very little can be done along these lines.

The generator should be housed in an effective shield. Louvers, windows, or other openings should be screened, the edges of such screening being securely bonded to the main shield. Plating to improve the conductivity of shielding and to improve the corrosion resistance of joints is advisable. Sufficient thickness of metal should be used to avoid current penetration. Contacting surfaces should be free of paint, dirt, or corrosion. Doors should be continuously bonded to the main shield around their entire periphery by contacting fingers or other suitable means. Door interlocks should be incorporated to prevent operation of the set when opened, as well as for reasons of safety.

It is good practice to protect internal components not associated with the generating circuits from high-frequency currents. This applies to control wires, meters, relays, low-frequency and d-c supply circuits, and so forth. Shielding and filtering of the generator often is simplified by the use of a separate internal shield, containing the high-frequency circuits only.

Where generators require transmission lines, it is recommended that they be designed for use with coaxial line. Other types of lines are a single shielded pair, 2-wire individually-shielded pair, 2-wire open line. In cases where the work circuit must be unshielded (as in some induction-heating installations), such circuits should be as compact as possible and located close to the generator. Open-wire feed lines should be short and closely spaced. If possible, they should be balanced to ground. When practicable, the work area should be enclosed in a screened booth.

A power-line filter should be incorporated in the generator; unshielded auxiliary circuits should be avoided, or else be effectively filtered. All metal pipes associated with water cooling, power supply, grounding, and similar connections should enter the installation at a single point. If this is not done, potentials across the shield surfaces, due to various small leaks, will cause currents such as I_8, I_9, and I_{10} to flow, see Figure 1. Such piping should be bonded to the shielding at the point of entry, in order that high-frequency currents will be effectively short-circuited and will not be conducted from the inside to the outside of the shield. Preferably such connections should approach from underground.

Finally, before a design is released for production, one of the performance tests should be a thorough check for high-frequency leakage with a sensitive probe, such as is shown in Figure 3. Such tests should be made over as wide a frequency range as possible, in order to locate harmonic or other spurious frequency radiation. If possible, the life expectancy and reliability of shielding devices should be checked. If appreciable radiation or poor design is discovered by such tests, every effort should be made at improvement, since this will lessen the problem of interference reduction for every installation that is made.

INSTALLATION

A preferred location for high-frequency equipment is on the first floor or in the basement of a building. The equipment should be as remote as possible from metallic ducts and flues, steam pipes, or power circuits which may pick up energy by capacitive or inductive coupling. It is very desirable to have the entire apparatus housed in a shielded room, although this is seldom practical. In any case, the installation should be as compact as possible, with emphasis on short, direct connections between units. Placing components of an installation on a large metal sheet is helpful.

The transmission line should be of the concentric or shielded-duct type. The outer conductor may be fabricated of copper, copper-plated steel, or aluminum. It is essential that the outer conductor be continuous, for example, where two sections of fabricated sheet-metal outer conductor are bolted together. Such joints and access covers must be fastened with screws, spaced not more than 3-to-4 inches apart. Large, radiating loop circuits may be avoided by running the line between units along the metal base of the installation.

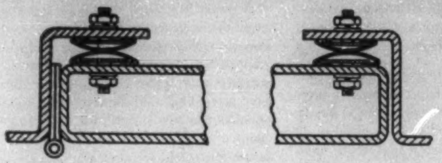

Figure 5. Spring contacting device with clamping strip for bonding doors

If the generator has been designed properly, the major source of interference will be the applicator, for the radio-frequency current and voltage here are apt to be quite large. Therefore, extreme care must be taken in its shielding. The applicator shield may be fabricated from copper, copper-plated steel, or aluminum, copper, or bronze screening (16-mesh). If the latter is used, a double-wall shield will give better results than a single-wall shield. However, adequate shielding frequently can be attained with a single shield at a lower cost if proper attention is paid to the details of construction. Shield currents usually can be reduced greatly by an internal partial shield. This appears to be particularly useful where the electrodes are large and stray capacities set up excessive shield currents. If possible, tuned circuits inside the shield should be attached to it at a single point only, to avoid circulating tank currents in the walls.

The applicator, wherever physically possible, must be completely enclosed by the shield with no openings or discontinuities in the bonding. Paint must be removed at all surfaces of contact, and these surfaces should be inspected at monthly intervals and any corrosion removed. Joints in the metal shield material may be made as in Figure 4. Typical door construction is shown in Figure 5, with continuous bonding around the entire periphery. The spring-like bonding strips are of beryllium-copper or phosphor-bronze construction. Brass or bronze weather stripping, or resilient metal mesh may be substituted for the construction shown. The shield should be as large as space and cost will permit. Under no conditions should the electrodes be spaced less than one foot from any part of the shield for powers in excess of 5 kw (output) and proportionately less for lower powers. For the megacycle range of industrial heating, generous overlap of metal sheeting is helpful in cases where hooked joints, or closely spaced fasteners, are impractical.

In some installations, mainly conveyor-belt operations, it becomes essential that openings be provided. In these cases, it is necessary to construct "vestibules" or "corridors" as shown in Figure 6. With a rectangular cross section as shown, the length *L* must be at least equal to the larger of the two dimensions *A* and *B*. Furthermore, the larger of the dimensions *A* and *B* should not exceed approximately 1/3 the wave length of the highest frequency to be suppressed. Such vestibules should not be located in wall surfaces carrying high currents, or in close proximity to a strong electric field.

Shielding of the applicator floor should not be overlooked. It is important that it be a continuous part of the whole shield, running underneath each of various enclosed components.

Control wiring must be kept out of the applicator wherever possible. If internal wiring becomes necessary, as large a proportion of the circuit as possible should be run externally and metal conduit employed throughout. Conduit should be terminated at both ends in a metal enclosure, junction box, or other shield fitting. Unfiltered wires should not be extended into the open. It has been recommended that the main power supply to the equipment pass through a line filter before leaving a conduit. This applies also to auxiliary power lines which may by-pass the main filter. The use of solid metal conduit or flexible metallic braid is to be preferred to spirally-wrapped metal sheathing (*BX*), due to eventual corrosion and poor contact between turns which will result in high-frequency leakage.

If shielding has been done properly, there is no necessity for grounding, other than for safety. For this purpose, a Standard Underwriters Safety Ground may be installed, or the conduit return to the main entrance switch may be used as a 60-cycle or d-c ground.

Certification of radio-frequency heating equipment is required by Part 18 of the FCC Rules and Regulations.[1] Limitations and test procedures are prescribed therein. Further information pertaining to these measurements may be found in "IRE Standards on Radio Wave Propagation–Measuring Methods, 1942,"[8] and "Measurement of Interference from Radio Frequency Heating Equipment."[9] If tests show the need for improved shielding, the location of trouble sources is facilitated greatly by a current probe, such as previously described. Methods of suppression as recommended in this report should be followed. It is pointed out that prevention by proper design is a much better policy than an extended series of cures after the installation is complete.

USE AND MAINTENANCE

The equipment always should be operated within its ratings as to power, electrode voltage, and frequency. Access panels, doors, and shields always should be in place when the unit is operating. Installers or manufacturers instructions should be observed. Warning notices to this effect may be posted near the equipment. Any changes in operation or repairs should be made in accordance with good engineering practices, and the user should ascertain that such changes have not nullified the results of initial tests for FCC certification.

A regular maintenance schedule should be followed to insure the proper operations of shielding devices. All contacts and bonding strips used in conjunction with openings should be cleaned whenever they show evidence of corrosion. Atmospheres corrosive to copper, bronze, aluminum, and so forth, are often prevalent in factories and may quickly reduce the

NOTE: SHIELDING CHARACTERISTICS OF THE INTERNAL OR EXTERNAL "VESTIBULES" ARE THE SAME. SELECTION OF EITHER FOR A SPECIFIC APPLICATION IS MAINLY BASED ON PHYSICAL CONSIDERATIONS.

Figure 6. Shield extensions for attenuation of radiation from openings

The length L must be greater than either A or B. A and B should be less than 1/3 the wave length of the highest frequency present efficiency of a shield by attacking bonding surfaces. Latches, screws, or other devices joining these surfaces should be tightened periodically. Such precautions may be incorporated as part of the regular maintenance schedule for the equipment.

Procedures where Interference Is Encountered

Faulty shielding, poor design, or other factors often cause leakage currents and excessive radiation from an installation after it is completed. Reduction to FCC limits is necessary. On the other hand, even though the field intensity from an installation may comply with the rules, it still is possible that interference with nearby communication services may occur under abnormal circumstances; this must be avoided.

Certain other circumstances may make an investigation of the radiation from high-frequency heating equipment necessary. Among these is the case of equipment, existing prior to the adoption of rules and regulations by the FCC, which does not comply with these rules and which must be modified before a specified date. In the meantime, if such equipment is found to interfere with any authorized radio services, steps to eliminate the interference must be taken. Another case is where the FCC has reason to believe that operation of a previously certified installation no longer meets regulations, and requires that the user renew his certification data.

Preliminary Checks

Where interference and/or excessive radiation is reported and a field intensity meter is not readily available, it often is possible to obtain temporarily a fixed or portable receiver of the communications type, which can give a relative indication of the field strength level (in comparison with other signals) and the nature of the transmission causing the interference. The following observations are recommended:

1. Does the interfering signal have the same frequency as, or bear a harmonic relationship with, the suspected generator frequency?
2. Does the interfering signal fade, indicating a location remote from the receiving point, or is it steady, suggesting a local signal?
3. Does the interfering signal have a characteristic tone or noise which is identifiable with the suspected source?
4. Does the interfering signal have a sequence of operation which is identifiable with the suspected source?

It often is possible to arrange an identifiable schedule of operation for the suspected generator, such as "2 minutes on—30 seconds off" during a known test period.

For a very approximate check on the interference level and to observe the effect of any steps taken as corrective measures, it is possible to use the "*S* meter" on the communications receiver. Roughly, such a meter is calibrated in steps of 6 decibels between successive *S* points, with a signal of 50–100 microvolts at the receiver terminals, corresponding to *S*9. This method should be used only as a temporary expedient. Calibration varies between manufacturers, and there is no way of correcting for the antenna length, current distribution, directional characteristics, matching, and height above ground, or the variation of receiver gain with frequency. These factors must be known in order to calculate the actual field strength in space.

A more accurate method of making field strength observations or noise measurements is with a field-intensity or noise meter. The various factors affecting calibration have been evaluated carefully for such meters, so that readings indicate the true intensity of the field arriving at the surface of the antenna. When the meters are used properly and their readings properly interpreted, they give good results.

Location of Sources

Having ascertained that interference and/or excessive radiation exists, the first step is to determine which unit is at fault, if several are suspected. Careful observations of frequency, operating sequences, or other characteristics may solve the problem quickly. They mav be supplemented through the use of direction-finding loop antennas, such as are incorporated on field-strength meters. Loops frequently are utilized by rotating them until a minimum reading is obtained. The direction from which the radiation is coming is then perpendicular to the plane of the loop. By taking a directional reading at each of two known points, the interference source may be determined by triangulation. Loop direction finders are subject to a 180-degree error because two minima appear as they are rotated through 360 degrees. They also may be inaccurate because of reflections from nearby conductors or other reflecting media, such as the ionosphere. It has been suggested that the errors due to reflection from local objects can be made small by orienting the loop for a maximum reading, as opposed to the method of minima described. In this case, the source of the radiation will be in the plane of the loop. In order to determine the maximum accurately, the loop may be turned both right and left from the maximum position to obtain equal small reductions in the reading. The average of the directions so obtained is the true direction of the source (with 180-degree sense ambiguity). In trying to triangulate the location of sources which are intermittent in operation, it is important to take simultaneous bearings from two points and to be sure that the same signal is being observed at both positions. Otherwise, large errors can easily result.

Dipole antennas may be similarly used to indicate direction of arrival. They are subject to ground, polarization, and reflection errors. The addition of a director or reflector (double dipole) to eliminate the 180-degree error, combined with the tuning procedure as described for loops, has been recommended to improve the accuracy of this type of direction finder. At frequencies above 18 megacycles, dipole antennas are the most effective means of receiving radiated energy.

Another search procedure is by a process of "homing" with a portable receiver. The radiating generator is "tracked down" by following along the direction in which the signal increases. The method is again handicapped to some extent by reflection, unless suitable precautions are taken.

Once the installation causing the interference has been spotted, the problem of reducing leakage is greatly simplified by locating faults in shielding with a current probe, as previously suggested. When the pickup loop L_2 of Figure 3 is brought close to a current leak in the shielding or filtering, a voltage is transmitted to the tuned circuit L_1C_1 and thence to the rectifier circuit, consisting of the crystal X, a filter R_1C_2, and a microammeter M. The rectifier converts the high-frequency current to direct current for deflecting the meter M. The tuned circuit functions both as a variable sensitivity and selectivity control. Leakage currents induce voltages in the pick-up loop by mutual induction. The entire unit is shielded in order to minimize body-capacity effects. Such a probe also has directional characteristics which are useful in plotting the main current paths, illustrated in Figure 1. This feature is best utilized by turning the loop for a minimum reading of the meter. The path of stray current then will be perpendicular to the plane of the loop. When available, noise meters and interference locators may be used for locating shield faults. More accurate quantitative data is obtainable in this way, but it often will be found that the simple probe described is entirely adequate.

Corrective Measures

Where the radiation is within FCC limitations, the interference to a service sometimes may be eliminated quickly by merely changing the frequency sufficiently to avoid any possibility of operation in the service channel. In some instances, it may be possible to place the frequency accurately in the channels assigned for industrial equipment by incorporating an automatic frequency-control device into the generator. When this is done, no special shielding is necessary other than for safety reasons. However, in a great many cases improved shielding, filtering, and bonding of the equipment are the only practical solution to a problem. The steps to be followed are similar to those discussed in previous sections of this paper.

Conclusion

Rules and regulations by the Federal Communications Commission governing radiation from industrial radio-frequency heating equipment have created a need for information on methods and practices which will minimize or reduce interference. Radiation is the result of currents flowing in unshielded conductors, which include equipment, shielding, metal frames, power feeders, and plumbing or other fixtures attached to the installation. The most practical method of locating sources of radiation is with a radio-frequency current probe. The magnitude of the radiation may be measured by means of a field-intensity meter. Among the devices suggested for eliminating interference are shields and filters. Shields should be continuous without gaps, poor joints, or unshielded openings. They should be made of a good conductor, although copper or bronze screen is effective, if care is used in the construction. Double shields provide extra protection but are not necessary in most cases. Filters are installed in unshielded wire circuits. In order that they be effective at high frequencies, the image impedance arrangement of components, and grounding must be selected with care. Principles of good engineering practice should be incorporated in the manufacture, installation, and use of radio-frequency heating equipment.

Discussion

C. W. Frick (General Electric Company, Schenectady, N. Y.): Mr. Klingaman's paper is a very good summary of the activities of committees set up by AIEE and the Institute of Radio Engineers and I have been very pleased to have participated in this work. Since such suggestions as I have had are in most cases already incorporated in this resume, I will take this opportunity to make a few comments on the general problem which is presented when new equipment is developed requiring for best performance the use of frequency extending into the radio spectrum. The problem is to operate such equipment without affecting radio communications adversely.

In the present paper the problem is treated largely from the standpoint of shielding. Dielectric heating lends itself very well to such treatment since in many cases the heating operations can be performed inside a shielded enclosure. In most cases of induction heating, even when the work coil is not well shielded, the radiation has been small because the exposed parts are poor radiators.

The AIEE Subcommittee on Induction and Dielectric Heating has been keeping track of interference complaints for induction and dielectric heating equipment. As compared with the total number of installations in service, the number of interference complaints has been very small.

Prior to the development of high frequency equipment for industrial heating, interference problems were encountered with other devices such as "wireless" record players and "gadgets" for the remote control of receivers by radio. The Federal Communications Commission adopted the "low-power rule" which limits the radio field intensity to a specified value at a distance proportional to the wave length used. This rule did not work for industrial heating and different limits were developed as referred to in the paper. Also, neither the "low-power" rule nor the industrial heating rules were suitable for diathermy equipment since that type of apparatus cannot ordinarily be shielded effectively. After considerable study some few frequency bands were assigned for this purpose. These bands also may be used for equipment in industrial and scientific service.

It may be noted that each time problems have come up an individual solution has been worked out. Because of the developments likely to occur in the future, thought should be given to a more general program. Since we cannot forsee what these future developments will be, it has been suggested that the radio spectrum be studied with a view to determining a series of frequency bands, spaced at reasonable intervals on the frequency scale which, if left free for industry to use, would meet the needs reasonably well over a period of years.

G. W. Klingaman: Mr. Frick has presented some of the background of the interference problem and emphasized several interesting points, which were somewhat neglected in the paper. The whole field of radio-frequency heating is still developing. Devices and techniques are constantly being improved and radiation from high-frequency heating equipment, which at first appeared formidably serious has been reduced to a satisfactory degree by standard engineering methods. The material presented in the paper summarizes the work of a number of groups (AIEE, Institute of Radio Engineers, and the National Electrical Manufacturers Association) on the interference problem, which it is hoped will be added to and improved in the future.

Measurements of Erythemal Energy

HOYT S. SCOTT
MEMBER AIEE

ATTENDANT to the growing popularity of solaria and increasing public acceptance of sources generating erythemal ultraviolet, there is a definite need in the field for a rugged, compact direct-reading meter that will measure the E-Vitons* per square foot in quite the same way that a footcandle meter measures lumens per square foot. The design of such a meter is discussed in this paper.

An accurate and accepted method of measuring erythemal ultraviolet is with a monochromator. The basic principle of operation is to pass the energy beam through an optical system, separating the energy into its spectral bands. The band desired is then passed through a slit and measured with a sensitive recorder. For the highest accuracy, warranted only in laboratory work, a double monochromator is needed. The double monochromator makes use of additional sets of optics and slits.[2] The advantage is its large energy-gathering powers, resulting in relatively large amounts of energy in any given wave length at the exit slit. Quartz optics are necessary for the transmission of erythemal ultraviolet. The weight of either single or double monochromators may be in the order of several hundred pounds.

When lower orders of accuracy are desired, the generally accepted practice is to use an instrument employing a special phototube. This may consist of a spectrally selective phototube without special filters, or a more general phototube with special filters. In either case heavy batteries and amplifiers are necessary. The fragility of phototubes, the weight of the batteries, and the instability of phototube calibration limit these instruments to nonportable operation.

From the foregoing, the disadvantages for field use are obvious, and a compromise was considered between a reasonable degree of accuracy for commercial application, and a light compact instrument that could be carried in the pocket.

In a solarium where only a partial degree of portability is desired and moderate weight and bulk is not a factor and where general commercial accuracy is sufficient, an amplifier and galvanometer-type moving element may be used. The best application for this is in conjunction with an optical system for projection on a screen.

In searching for such a device, the use of phototubes was considered to be practical only where portability was relatively unimportant. To this end it is believed that selenium light cells with suitable filters present a more practical approach.

---

*E-Viton: A unit employed to express the health and erythema value of radiations above 2,800 Angstrom units, such as found in natural sunlight, while erythemal flux is that quantity of radiant energy which produces as much temporary reddening as 10 microwatts of energy at 2,967 Angstroms. One E-Viton per square foot is the same as 0.01 erythemally-weighted milliwatts per square foot or 0.01076 erythemally-weighted microwatts per square centimeter.

Several very fine types of meters are described by Luckiesh,[2] but for various reasons did not meet the author's requirements.

The barrier-layer type of light-sensitive cells, which become sources of electric energy when activated by energy within their sensitivity range, offer the attractive possibility of dispensing with batteries. They are subject only to the limitation of their spectral sensitivity range and the magnitude of their electric output. Available barrier-layer cells are sensitive to radiant energy from 2,800 to 8,000 Angstrom units, with a maximum response at about 5,800 Angstrom units. While theoretically they could be used to measure directly the 2,800–3,200 Angstrom-unit erythemal energy, their tenfold greater sensitivity at 5,200–6,000 Angstrom units provides a greater cell output even after very selective filtration and a wave length conversion by fluorescence. It has been found possible to connect barrier-layer cells in a series–multiple arrangement to provide sufficient output to give a full-scale deflection of a 0–1 microammeter with such incident energy as is transmitted by the combination of filters and fluorescent phosphors described hereafter.

The primary design problem was that of a combination of filters and a light-sensitive material simulating closely, in over-all response to radiant energy, the skin's erythemal sensitivity, which is considered an index of its beneficial and tanning reaction.

The secondary problem was that of measuring the output of the above filters and fluorescent phosphor with a combination of filters and light-sensitive cells, transmitting and sensitive only to the energy output of the primary filters and phosphor and not responsive to any ultraviolet, especially the 3,200–3,800 Angstrom-units region, or to any visible and infrared of wave length longer than 6,300 Angstrom units, which may have originated from the same source being measured and may have been transmitted by the primary filters and phosphor.

The meter consists essentially of light-sensitive barrier-layer-type cells, with proper correction filters, and a microammeter, as shown in Figure 1. In order to obviate possible solarization of the various filters, the entire device, consisting of explorer unit, leads, and microammeter, is contained in a convenient opaque carrying case, as shown in Figure 2. The combination of light-sensitive cells, similar to those used in the ordinary light meter, and

the filters used in conjunction with them are shown in Figure 3. The filters when assembled form a compact package. A diagrammatic sketch of these elements and their functions is shown in Figure 4(A). The details of each element are hereinafter described.

Prefilter

The selective filtering is accomplished by the use of a first filter, red-purple Corning number *9,863*,[3] which absorbs energy above 4,100 Angstrom units and transmits near ultraviolet and visible violet below 4,100 Angstrom units. The transmission characteristics of this first filter is shown in Figure 5(A). Unfortunately, this filter does transmit a slight amount of energy in the near infrared which must be absorbed by the other filters. See Figure 5(Y).

The second filter in the prefilter is Corex *D* Corning number *9,700*.[3] This transmits wave lengths above 2,500 Angstrom units (extremely small amount at 2,537 Angstrom units), but absorbs those below 2,500 Angstrom units. See Figure 5(B).

The prefilter group, in combination with the magnesium tungstate (Figure 5(C)), phosphor transmits the greater part of the energy between 2,800 and 3,200 Angstrom units, a small amount as low as 2,500 and as high as 3,400 Angstrom units plus the small amount of infrared mentioned above.

The net result of the two filters and the

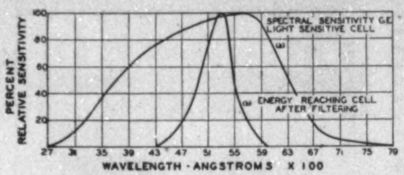

Figure 7 (above). Relative sensitivity of General Electric Company light-sensitive cell

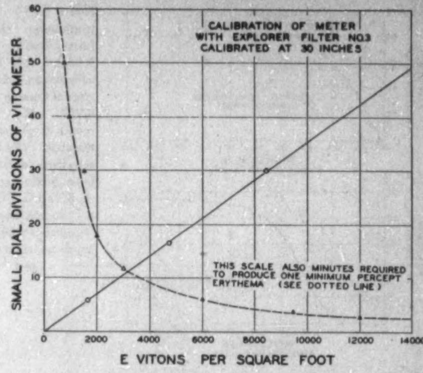

Figure 9. Typical calibration showing linearity, also time in minutes versus intensity, to obtain 1 minimum perceptible erythema

phosphor response is a relative selectivity curve shown in Figure 5(X). The significance of the shaded area will be explained later. This selectivity-sensitivity curve is arrived at by taking the product of Figures 5(A) and 5(B) transmission superimposed over that of Figure 5(C), combining the transmission of Figures 5(A) and 5(B) and the sensitivity of Figure 5(C), then multiplying by Figure 5(C), using the maximum value as 100 per cent. The result should be compared with the erythemal effect curves, Figure 8.

The Phosphor Function

The phosphor unit may be made using a number of materials, but magnesium tungstate was found to be the most satisfactory for use with the General Electric Company cell, catalog number *88X565*. The relative response of this phosphor when used with butyl acetate is given for various coating thicknesses in Figure 4(B).

The phosphor serves two functions. First, it is most sensitive in the 2,850 Angstrom-unit band, thereby generating visible light from approximately 3,600 to 6,700 Angstrom units for the activating of the cell, Figure 4(C). Second, it acts as a nonselective neutral filter from 3,400 up through 7,600 Angstrom units. From the curves in Figures 5(A) and 5(B), it can be seen that near ultraviolet and visible energy will be transmitted by filters *A* and *B*.

Figures 5(A) and 5(B) shows transmitted energy in the range of 2,500 to 4,100 Angstrom units to excite the magnesium tungstate phosphor. This phosphor acts as a neutral filter, Figure 4(D), to absorb whatever visible energy might be transmitted by filters numbers *9,863* and *9,700*. Figure 5(C) shows to what wave lengths magnesium tungstate responds. Figure 4(C) shows the resultant visible wave lengths generated.

The combined filtering action of filters *A* and *B*, in addition to the filtering action of the phosphor itself, over and above its primary purpose as a wave-length convertor, is shown in Figure 5(X) as a selectivity factor.

From the shaded portion of the selectivity curve of Figure 5(X), it can be seen that a small amount of near ultraviolet from 3,200 to 3,400 Angstrom units does fall on the tungstate phosphor. This amounts to slightly over 2 per cent of the generated. The amount of visible light generated from the phosphor by this spurious excitation is not shown. It is felt that it can be disregarded due to its low order, as shown on the sensitivity curve of the tungstate, Figure 4(C).

In addition to the above, there is a small amount of near infrared, Figure

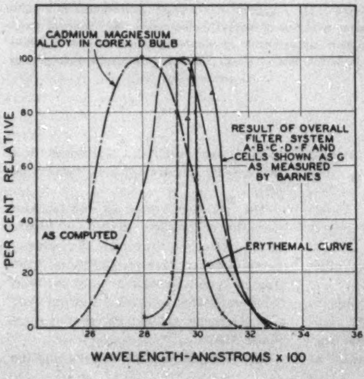

Figure 8 (left). Over-all spectral response of meter to erythemal curve. For comparison, response of cadmium magnesium alloy phototube is shown[5]

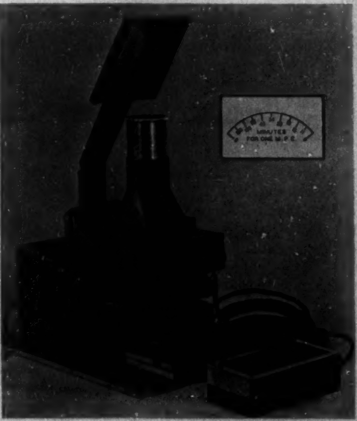

Figure 10 (right). Optical projector and calibration in minutes for minimum perceptible erythema, for use in solarium

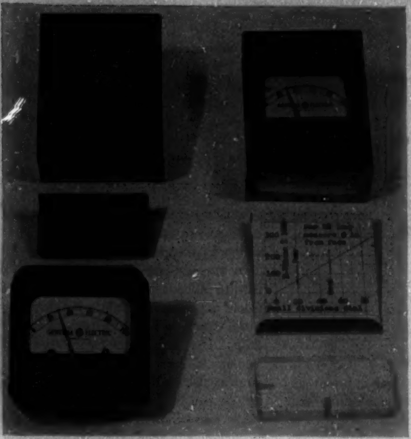

Figure 11. Small-size lower-sensitivity erythemal meter for measuring outputs at short distances

5(A). This infrared, originally transmitted by filters *A* and *B*, also is transmitted by the phosphor. See Figure 4(D).

Because of the infrared energy transmission of the prefilter and phosphor, as well as the transmission down to 2,500 Angstrom units, Figure 5(X), two additional filters are required. These are described as post filters.

Post Filter

The first element in the post filter, Figure 6(D), is a thin film of methyl methacrylate and serves the major purpose of protecting the phosphor coating, and secondarily offers free passage above 3,600 Angstrom units in the visible range. Because of the energy remaining in the range from approximately 2,500 to 2,800 Angstrom units as indicated in Figure 5(X), it is necessary to provide a second filter, Chromex number *2,324*. This is a plastic of British manufacture. The transmission characteristics of Chromex number *2,324* are shown as Figure 6(E). Because the previous filters have not absorbed the incident infrared energy, the third post filter is used with transmission characteristics shown in Figure 6(F). This is Corning number *4,010* sextant green.[3] The net result of the post-filter arrangement is to give energy transmission in the visible range from approximately 4,300 to 6,300 Angstrom units, and is shown in Figure 6(X-2). It is only this energy that activates the light-sensitive cell. Figure 7 shows how the curve in Figure 6(X-2) compares with the spectral sensitivity of the General Electric cell.[4]

Comparing the over-all spectral characteristic of the combined prefilter phosphor and post filter with the erythemal curve, Figure 8, it can be seen that weighting factors can be disregarded, as the meter follows the erythemal curve closely enough for practical purposes even though the sensitivity factor is slightly greater at 3,050 Angstrom units than theoretically would be desirable. Ultraviolet at that wave length is effective in producing dark tanning and hence may be included properly in the measurement of effective energy from a sunlamp.

Cells

In one of the meters, Figure 3, four standard General Electric cells, catalog number *88X565*, are used. The cells are connected in series-parallel in order to obtain the optimum energy transfer, as it is important to match the impedance of the cells to the impedance of the meter.

Moving Element (Meter)

The current delivered is in the order of a microampere. Many difficulties present themselves in the selection of a moving element that is sufficiently sensitive but still rugged enough to be carried in a portable manner. In view of the usual transportation handling problems, a double-suspension meter was selected. The meter used in the original prototype had 0–3-microampere full-scale deflection. One of the unique features in this meter is two push buttons, one to eliminate damping, bringing the pointer quickly to zero; the other "push to read." See Figure 1. A typical calibration curve, Figure 9, shows the linear characteristics. Superimposed on this curve is a curve indicating the minutes necessary for one minimum perceptible erythema for a given intensity. The foregoing statements cover the assembly of a filter exploring pad with its accompanying moving element. It is desired to show how a sensitive meter for field use might be constructed that would follow reasonably close the erythemal curve and measure the erythemal viton intensities without use of weighting factors.

For the measurement of erythemal intensities of commercial sunlamps at close distances (30 inches), a much lesser degree of sensitivity can be tolerated. A single light cell and a 0–8 microammeter with the above filter has been found to be satisfactory. See Figure 11.

A practical example of the use of the meter is in the "sun and star room (Sky Cabana)" of the Senator Hotel, Atlantic City, N. J., where the guest determines the duration of exposure of erythemal ultraviolet for minimum perceptible erythema in the various basking locations. The exploring pad is connected to a cord and plug associated with various convenient outlet jacks along the wall. An optical system, Figure 10, is used to project a scale calibrated in minutes on a screen at the end of the solarium.

No Discussion

Saving Time in Testing Life of Incandescent Lamps

W. R. PURCELL
NONMEMBER AIEE

THE heart of any technique of controlling quality during manufacture is skillful and scientific trouble shooting. To be scientific, the trouble shooting procedure should: leave the process alone when there is no trouble; apply corrective action when there is trouble; and apply such corrective action promptly while the trouble still exists and before many units of substandard quality have been manufactured.

One of the most useful techniques for determining whether there is trouble to shoot is the Shewhart control chart for measurements. In this technique, limits are set for the average and range of the measurements on periodically drawn samples. As long as the statistics continue to fall within the limits, it is presumed that there is no trouble and that the process should be left alone. As soon as a statistic falls outside the limits, there is strong evidence of trouble and corrective action should be applied. How promptly the corrective action can be applied depends on how quickly the measurements can be made and the statistics computed.

In most applications of this control chart technique, measurements can be made promptly. Thus the third element of scientific trouble shooting, prompt action, usually can be made a part of the procedure. In certain cases, however, this is not so, and the time required to make the measurements substantially reduces the value of the technique. An outstanding example is the test of life, in which neither the average nor the range can be computed until the last unit of the sample has reached the end of its life.

In many cases, this difficulty has been partially overcome by increasing the severity of the life test. A classic example is the shortening of the life of incandescent lamps from 1,000 hours to about five hours by burning them at 150 per cent of rated voltage. Even at this acceleration, however, it often requires seven or eight hours to burn out the last lamp of a sample; yet the final result might yield an average so small or a range so great that need of corrective action is indicated. Attempts to accelerate the life test further cause abnormal arcs and do not give a true picture of normal life. Since the test cannot be further accelerated, it is necessary to accelerate the statistics.

Symbols

UCL_m = upper control limit for medians
CL_m = central line for medians
LCL_m = lower control limit for medians
UCL_s = upper control limit for shortest
CL_s = central line for shortest
LCL_s = lower control limit for shortest
M = average of medians
S = average shortest
n = sample size
σ_m = standard deviation of medians
σ_s = standard deviation of shortest
σ' = standard deviation of population
K = constant relating mean first statistic to population standard deviation
C_s = constant relating σ_s to σ'
C_m = constant relating σ_m to σ' in odd-size samples
$\sigma_{n/2}$ = standard deviation of (1/2) nth statistic
C = constant relating $\sigma_{n/2}$ to σ'
$\sigma_{\{1/2\}\{[n/2]+[(n/2)+1]\}}$ = standard deviation of mean of (1/2) nth and $[(n/2+1]$ statistics
$r_{[n/2],[(n/2)+1]}$ = correlation coefficient between (1/2) nth and $[(n/2)+1]$ statistics
T_1 = constant relating $3\sigma_m$ to $(M-S)$
T_2 = constant relating $3\sigma_s$ to $(M-S)$

In conventional statistics, average is used to indicate a shift in the level of the whole population; range is used to indicate a change in population dispersion. A shift in level also can be indicated by the median life, or central failure in the sample; a shift in level or change in dispersion can be indicated by the shortest life, or first failure in the sample. The use of median and shortest as statistics substantially accelerates the results. A tendency toward short life which is indicated by the sample is indicated quickly. It is not necessary to continue the test beyond the median, and corrective action can be started promptly.

Before adopting these new statistics a preliminary study of the inherent frequency distribution of incandescent lamp life was made. Table I is a typical set of data accumulated before control was established. The data indicate the following conclusions:

1. In the long run the average of the medians coincides with the average of the averages.
2. Both of these statistics are about half way between the average shortest life and average longest life.
3. The differences between median and average in individual samples are not significant.*

From these conclusions the assumption was made that the inherent frequency distribution of incandescent lamp life is substantially normal.

In control charts there is a central line about which the statistics are expected to scatter in random fashion just as long as there are no shifts in population center or dispersion.

This central line is located at the long-term average of the statistic. Extending this technique to these new statistics, the central line for medians is located at the average median, and the

Paper 49-187, recommended by the AIEE Committee on Production and Application of Light and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer General Meeting, Swampscott, Mass., June 20–24, 1949. Manuscript submitted November 10, 1948; made available for printing May 3, 1949.

W. R. PURCELL is with Sylvania Electric Products, Inc., Salem, Mass.

*Average of the range is 410 hours. From this, the standard deviation of units (σ') is about 176; standard deviation of averages (σ_a) about 80. The average of the absolute differences (40) is only one-half of one standard deviation of averages; the greatest difference (130 in sample 19) is only 1.62 standard deviations of averages.

central line for shortest is located at the average shortest.

Conventional limits allow for variations in the statistics which are not significant. These insignificant variations are due to the constant system of chance causes in the process and operation of chance in sample selection. The control limits are placed at three standard deviations of the statistic above and below the central line of the statistic. A statistic beyond the control limits is then very unlikely if chance is operating alone, and is therefore considered conclusive evidence that some other dominant cause is affecting the process.

Using this same procedure, control limits for medians are placed thus

$$UCL_m = M + 3\sigma_m \tag{1}$$

$$CL_m = M \tag{2}$$

$$LCL_m = M - 3\sigma_m \tag{3}$$

and control limits for shortest life are placed thus

$$UCL_s = S + 3\sigma_s \tag{4}$$

$$CL_s = S \tag{5}$$

$$LCL_s = S - 3\sigma_s \tag{6}$$

To compute the values of σ_m and σ_s, reference was made to a table of order statistics.[1] This table gives the means and standard deviations of the first, second, third, and so forth, statistics of small samples, with reference to the mean and standard deviation of the population.

Confining our attention to the normal distribution, these tables yield, first, a constant (here called K) relating the average of the first statistic (shortest life) to the population standard deviation thus

$$S = M - K\sigma' \tag{7}$$

Thus the population standard deviation is given by

$$\sigma' = (M - S)/K \tag{8}$$

Second, the tables yield another constant (here called C_s) relating the standard deviation of the first statistic (shortest life) to the population standard deviation thus

$$\sigma_s = C_s\sigma' \tag{9}$$

Combining equations 8 and 9 we have

$$\sigma_s = (C_s/K)(M - S) \tag{10}$$

For odd-size samples, the tables yield another constant (here called C_m) relating the standard deviation of the median to the population standard deviation thus

$$\sigma_m = C_m\sigma' \tag{11}$$

Combining equations 8 and 11 we have, for odd-size samples

$$\sigma_m = (C_m/K)(M - S) \tag{12}$$

For even-size samples, the tables yield another constant (here called C) relating the standard deviation of the (1/2) nth statistic to the population standard deviation thus

$$\sigma_{(n/2)} = C\sigma' \tag{13}$$

Combining equations 8 and 13 we have

$$\sigma_{(n/2)} = (C/K)(M - S) \tag{14}$$

In this case, however, it is preferable, in order to avoid confusion, to consider the median as the mean of the $n/2$ and $(n/2) + 1$ statistics, thus retaining the same central line. We have, then, for even-size samples

Table I. Typical Data for Life of Incandescent Lamps in Hours before Establishment of Control

Each sample contains 5 lamps

10	1.5388	0.5868		0.3886	0.83

$$\sigma_m = \sigma_{(1/2)\{[n/2]+[(n/2)+1]\}} \tag{15}$$

Now the variance of the sum of two statistics a and b is given by

$$\sigma^2_{a+b} = \sigma_a^2 + \sigma_b^2 + 2r_{a,b}\sigma_a\sigma_b \tag{16}$$

In our case our two statistics are the $n/2$ and $(n/2) + 1$ values. Since the distribution is normal, we know by symmetry that these two variances are equal. Therefore

$$\sigma^2_{[n/2]+[(n/2)+1]} = 2\sigma^2_{(n/2)}[1 + r_{(n/2),(n/2)+1}] \tag{17}$$

Since we want the variance of the mean of $n/2$ and $(n/2) + 1$, and since the variance of a half-statistic is one quarter of the variance of the whole statistic, we have

$$\sigma^2_{(1/2)\{[n/2]+[(n/2)+1]\}} = \sigma^2_{(n/2)}\{1 + r_{(n/2),[(n/2)+1]}\}/2 \tag{18}$$

or, in terms of standard deviations

$$\sigma_{(1/2)\{[n/2]+[(n/2)+1]\}} = \sigma_{(n/2)}\sqrt{\{1 + r_{[n/2],[(n/2)+1]}\}/2} \tag{19}$$

Combining equations 14, 15, and 19, we have, for even-size samples

$$\sigma_m = (C/K)\sqrt{\{1 + r_{[n/2],[(n/2)+1]}\}/2} \times (M - S) \tag{20}$$

Table III. Values for Computation of Median Life and Shortest Life Control Limits

For Substitution In:
$UCL_m = M + T_1(M - S)$
$LCL_m = M - T_1(M - S)$
$UCL_s = S + T_2(M - S)$
$LCL_s = S - T_2(M - S)$

Sample Size n	T_1	T_2
3	2.38	2.65
4	1.50	2.04
5	1.38	1.72
6	1.10	1.53
7	1.02	1.39
8	0.87	1.29
9	0.82	1.21
10	0.73	1.14

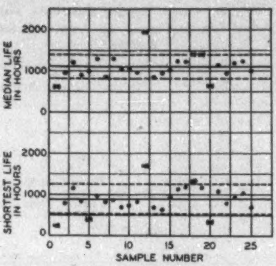

Figure 1. Control chart of data in Table I—control not established

Values of K, C_s, C_m, C, and $r_{[n/2],[(n/2)+1]}$; reproduced from the paper cited, are given in Table II.

For simplicity, we establish new constants T_1 and T_2 such that

$$T_1(M-S)=3\sigma_m \tag{21}$$

and

$$T_2(M-S)=3\sigma_s \tag{22}$$

Combining equations 21 and 12, we have, for odd-size samples

$$T_1=3C_m/K \tag{23}$$

and combining equations 21 with 20, we have, for even-size samples

$$T_1=(3C/K)\sqrt{\{1+r_{[n/2],[(n/2)+1]}\}/2} \tag{24}$$

Combining equations 22 with 10, we have, for any sample size

$$T_2=3C_s/K \tag{25}$$

Values of T_1 and T_2 have been calculated, using equations 23, 24, and 25 and constants in Table II, and are tabulated in Table III for sample sizes from 3 to 10.

The final equations for central lines and control limits are

$$UCL_m=M+T_1(M-S) \tag{26}$$

$$CL_m=M \tag{2}$$

$$LCL_m=M-T_1(M-S) \tag{27}$$

$$UCL_s=S+T_2(M-S) \tag{28}$$

$$CL_s=S \tag{5}$$

$$LCL_s=S-T_2(M-S) \tag{29}$$

Example from the data in Table I

$M=1{,}100$

$S=890$

$n=5$

from Table III, for $n = 5$

$T_1=1.38$

$T_2=1.72$

The control limits and central lines are

$UCL_m=1{,}100+(1.38)(1{,}100-890)=1{,}390$

$CL_m=1{,}100$

$LCL_m=1{,}100-(1.38)(1{,}100-890)=810$

$UCL_s=890+(1.72)(1{,}100-890)=1{,}250$

$CL_s=890$

$LCL_s=890-(1.72)(1{,}100-890)=530$

Another most interesting application of order statistics is destructive tests has been developed elsewhere.[2]

The statistics of median and shortest have been in use at Sylvania for incandescent lamp life test since 1945.

One advantage in the use of these statistics is the saving in time and facilities required for test. A second advantage is the elimination of the calculation of averages and ranges. There is one disadvantage. For the same sample size, median is 10 per cent to 25 per cent less stable, and therefore as a control statistic less sensitive, than the average.

The great advantage is the speed of the corrective action, which is the very purpose of the whole testing procedure. Furthermore, the fastest action is taken when most needed; that is, when life is short.

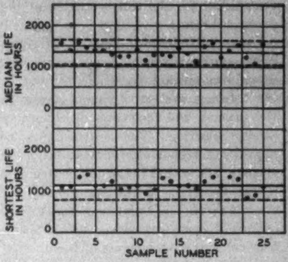

Figure 2. Control chart—control established

Figure 1 (control chart of the data in Table I) illustrates this especially for samples 1, 5, and 20. Action on these statistics was possible in the accelerated equivalent of 270, 380, and 340 hours (that is, slightly over $1^1/_2$ hours). Action on conventional statistics would have been delayed until the accelerated equivalent of 740, 1,090, and 880 hours, respectively, or about $4^1/_2$ hours.

Figure 2 illustrates the appearance of charts based on these statistics after control has been established. The increase in average life and improvement in uniformity have been very gratifying.

Economic Loading of a Transformer System

D. L. LEVINE
MEMBER AIEE

H. E. SMITH
MEMBER AIEE

Synopsis: Loading of transformers must be guided by both economic and thermal limitations. For economic limitations, the costs of installation and operation must be evaluated for each type of transformer. Thermal limitations should be in accordance with the present ASA Loading Guide.[1] Transformers subject to both normal and emergency operating conditions should have thermal limitations established for both conditions. Transformer loading must be within the thermal limitations of connected equipment. Voltage regulation requirements may limit the loading of distribution transformers.

IN 1942 the first AIEE operating guide for transformers was issued. This guide grew out of all the knowledge of the industry on the life characteristics of transformer insulation. It was based on everything from laboratory tests on insulation to successful operating experience with large numbers of transformers over as many years as transformers have been used. Since 1942 there has been more intensified study of insulation aging under laboratory conditions. Also, there has been operating experience with transformers at ever-increasing load levels. In 1948 the operating guide was reissued in its second revision since 1942 as the ASA C57.32 "Guide for Loading Oil-Immersed Distribution and Power Transformers."[1] The guide represents the best that is available in the industry and it can serve as a sound basis for thermal loading of transformers of any operating system.

But actual application to an existing system is a problem that the guide cannot cover. That is an individual problem that each company must take upon itself, if it is to make the best use of its own transformers. It is the purpose of this paper to set forth how one large operating company effectively increased the loading on its transformer system by application of the principles of the ASA operating guide to its own needs and conditions.

Economic Study

The entire program was based on the acceptance of the guide as the criterion for thermal loading. However, before instituting such a program it was necessary to show that it was economically proper to do so. Somewhere there had to be a balance between thermal loading and economic loading and it was necessary to find that balance before making any drastic change in loading practices.

For a large system, an economic study must be made applicable to many varying conditions. To do this, the study must be general and cover a range of all the important variables in the problem. For the study as made, the following major variables were considered:

1. Installed cost per kilovolt-ampere.
2. Life of equipment.
3. Annual fixed charges.
4. Operating efficiency.
5. Ratio of copper losses to core losses.
6. Cost of losses.
7. Load cycle.

Installed Costs per Kilovolt-ampere

The installed cost per kilovolt-ampere in the light of present rapid change in construction costs can be almost anything depending on what is considered to be included in the transformer installation. To the bare transformer cost must be added the cost of installation with all associated equipment. Also, for substation transformers, the structural, building and land costs must be added to give the total cost per kilovolt-ampere. In comparative studies it is best to use incremental cost, that is, the cost per kilovolt-ampere of the increase from one standard size to the next. Because of the wide range of such costs, this study covers the general case, with the present average incremental cost per kilovolt-ampere as unity.

Life of Equipment

The question of average life of equipment had to be considered in order to answer the obvious question of what change a policy of increased loading would make. Did transformers wear out or were they discarded because of obsolescence under the existing loading policy? A statistical survey showed that no exact answer could be given to this question. The equipment being dealt with is generally considered to have an average normal life of 30 years or more, and the age of most of the system is less than that, so that statistically no accurate conclusions can be drawn from our own experience.

Rate of Annual Fixed Charges

The rate of annual fixed charges varies over different portions of a power system. Since combinations of associated equipment were being worked with, it was necessary to use a combination of various figures. This includes an annual depreciation charge. If a loading level beyond that for normal thermal life is chosen, then this annual depreciation rate will increase accordingly. An annual unit fixed charge rate was used, to apply only to loading for normal total life.

Operating Efficiency

The operating efficiency of the transformer is a controlling factor in an economic study. For newer large-size power transformers, the efficiency at nameplate rating is better than 99 per cent. For

D. L. Levine is Senior Engineer and H. E. Smith is Distribution Planning Engineer, Commonwealth Edison Company, Chicago, Ill.

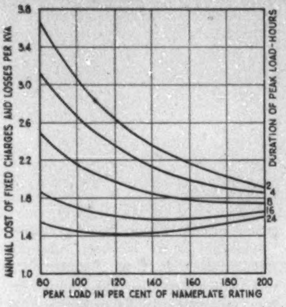

Figure 1. Effect of peak load and peak duration on cost of operation

older units and for distribution transformers the efficiency will run closer to 98 per cent. A range of efficiencies was covered in the study, but for the general case an efficiency of 99 per cent was used.

Ratio of Copper Losses to Core Losses

For variable loading of transformers, the ratio of copper losses to core losses fixes the rate of change of efficiency with load.

This ratio varies with size, type, and year of manufacture of transformers. The study includes a range of ratios from 4/1 to 1/1. For the general case, the loss ratio 2/1 as applicable to newer power transformers was used.

Cost of Losses

It is difficult to fix a reasonable total cost of losses on electric equipment. The coal cost, which may be ascertained without much difficulty, is but a part of the total cost. Base load station cost per kilowatt-hour can be calculated by using total kilowatt-hour output per year and total annual cost of operation, including fixed charges. It is necessary to add to this the fixed charges and the operating cost of that part of the total system which supplies the losses at any particular point on the system. The cost varies for core losses and load losses and for location on the system.

Also, the practice of shutting down portions of large power banks during low-load periods complicates the handling of core losses.

Here again the study was put on a unit basis with a general average cost of losses taken as unity. A range of costs from 0.4 to 1.6 times unity was considered.

Load Cycle

Load cycle is a variable which cannot very well be averaged. In our study it was assumed for purposes of simplification that all load cycles were of the rectangular block form and that the peak occurred once a day. A range of peak duration from two hours for residential lighting load, to 24 hours for base load station transmission transformers was considered. Off-peak load was assumed to be steady at 25 per cent of peak. With rectangular load cycles, this fixed both load factor and loss factor as functions of duration of peak load during a 24-hour period. Results from this method checked with a reasonable degree of accuracy with detailed summaries on an annual basis made on various types of loads on our system.

Overloading with Less than Normal Life

One obvious question that had to be answered was whether or not loading with less than normal life was justifiable. Simply stated the question is this: "To obtain one per cent additional load beyond the limits for normal life from an installation, is it better to overload one per cent or to buy one per cent additional equipment?" A simple answer is obtainable by balancing the increased depreciation charge of the first method against the increased installed cost of the second method. Based on the accepted thermal data of the operating guide, a one per cent increase in load gives a one degree centigrade increase in maximum temperature. Also, a one degree centigrade increase in temperature indicates about nine per cent decrease in life. This would mean a corresponding increase in depreciation charges and in annual fixed charges. The cost of one per cent added capacity to serve one per cent added load will usually be less than the added cost due to shortened life of the existing capacity for one per cent load beyond the load for normal life.

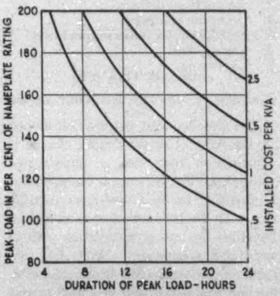

Figure 2. Effect of installed cost on economic peak load

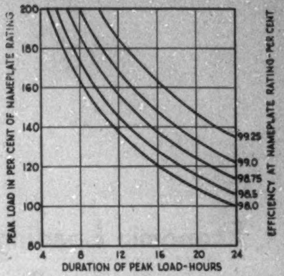

Figure 3. Effect of transformer efficiency on economic peak load

However, where the end of space capacity for a substation, for example, has been reached and increment cost for added kilovolt-ampere capacity must include building costs, daily loading for less than normal life may be cheaper than adding capacity.

It should be noted that these limitations of loading for normal life apply only to normal loading. Emergency loading with some sacrifice of normal life must be analyzed separately.

General

In order to take care of the many possible conditions of cost and loading, the basis of comparison was taken as the average total cost of losses and fixed charges for a kilowatt-year of output. The range of such costs as affected by duration and magnitude of peak load with all other factors constant is shown by Figure 1. It can be seen that the cost curves are quite flat where there is a point of minimum cost. This indicates that, for practical purposes, maximum economy may be obtained over a load range of 20 to 30 per cent.

For a complete study it is necessary to consider the effect of variation in the constants which have been fixed for the average condition shown by Figure 1. To lessen the total data to be compiled, all other curves were drawn to show only the maximum economic load for each set of governing conditions. Method of calculation of the curves is given in the Appendix.

As has been stated previously, all data were considered for a range of hours' duration of peak load, since this could not well be averaged.

Figure 2 shows the effect of installed cost per kilovolt-ampere on economic peak load with other factors remaining constant. This is a most significant set of curves showing as it does the effect of increased installation costs of the last few years on economic peak load.

Figure 3 shows the effect of transformer efficiency on economic peak load. Even at 98 per cent efficiency, economic loads are all above 100 per cent of nameplate rating.

Figure 4 shows the effect of change in ratio of losses on economic peak load. This effect should be given special attention where small transformers with high forced-cooled ratings are being used for normal high loads.

Figure 5 shows the effect of variations in cost of losses on economic peak load. Again, the loads are higher than practical thermal limits, but the figure shows what an increase in cost of losses to match present costs would do in the way of bringing down economic loads.

Figure 6 shows how daily loading with some sacrifice of normal life may be justified where installed cost for added capacity would be considerably higher than the installed cost per kilovolt-ampere of existing equipment.

Obviously these curves cover only a few of the average conditions of variables involved. For any specific case the formulas given in the Appendix may be applied.

These curves bear out the main point that the magnitude of losses and cost of losses are important factors in economic loading but that with present construction costs, installed cost is the main controlling factor. Unless cost of losses is much higher than normal or installed cost is lower than average, economic loading is higher than thermal limitations.

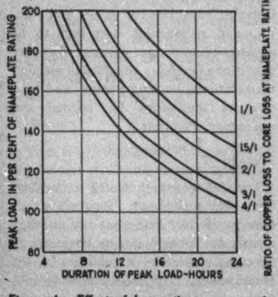

Figure 4. Effect of loss ratio on economic peak load

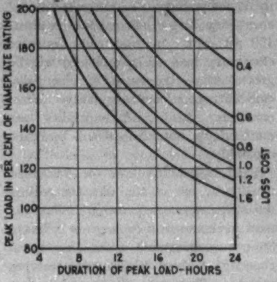

Figure 5. Effect of loss cost on economic peak load

THERMAL LOADING

The acceptance of the ASA "Guide for Loading Oil-Immersed Distribution and Power Transformers" C57.32—1948[1] as the criterion for safe thermal limitations of a transformer still leaves the interpretation and application to the user.

For thermal loading transformers must be divided into two groups. On the Commonwealth Edison Company system most station and substation transformers are operated in parallel banks. Maximum load on a bank is limited to that load which can be carried with the largest unit out of service because of an equipment failure. Failures are infrequent and such operation is treated as a rare emergency that justifies operation with moderate sacrifice of life expectancy. Since either the normal or the emergency condition may be the limit, both conditions must be studied.

For all distribution transformers and for power transformers that are not banked, there is only the normal operating condition to consider. Also, the total number of such transformers is much larger than the number of substation transformers. For this reason, the thermal loading will be covered in two parts, large power transformers and distribution transformers, although much of the data applies to both groups.

Power Transformers

NORMAL LOADING

For normal loading for normal life expectancy, the guide gives definite consideration to actual temperature rise of the transformer, ambient and load cycle.

For practical operation all large power transformers are assumed to have a 65 degree centigrade hottest spot copper temperature rise at nameplate rated load unless test data shows otherwise. Test data may be factory heat runs showing a rise less than 65 degree centigrade or they may be tests of an installed transformer showing a temperature rise greater or less than 65 degree centigrade because of cooling conditions other than those of the original design. Such changes may be a limited supply of air or water to give poorer cooling, or the addition of radiators, fans or other cooling facilities which make the transformer better thermally than its original design. For large power transformers not already fan-cooled, the use of auxiliary fans for added cooling should be a first step in increasing transformer capabilities.

Ambient temperature is always a subject for discussion. Theoretically, load ratings should vary through the year with ambient temperature. Practically, too many ratings complicate operation of a large system. It was found best to limit capabilities to winter and summer operation. For summer operation, a temperature of 30 degree centigrade was chosen as outdoor ambient. Actually this is the normal average maximum temperature for midsummer. On a life basis 30 degree centigrade can be considered conservative for both normal and emergency use without any special higher ambients for hot summer weather. For winter it was necessary to use an ambient that would allow for higher temperatures at both ends of the winter season. Also, for substation transformers it was necessary to allow for partial enclosures. A seasonal winter ambient of 10 degree centigrade was accepted, with lower ambients recognized for specific Christmas peaks. Comparably, cooling-water temperatures of 25 degrees centigrade for summer and 5 degrees centigrade for winter are used, based on 20-year water supply records.

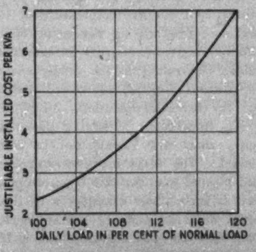

Figure 6. Justifiable installed cost per kilovolt-ampere where daily load exceeds load for normal life

For indoor installations, ambients are based as nearly as possible on actual records. Accepted policy is to ventilate indoor installations in summer, and to heat them in winter for personnel comfort. Where equipment is operated without attending personnel, ventilation is provided when necessary, but summer ambients are allowed to go to 40 degrees centigrade. Such temperatures may necessitate derating indoor transformers, but cooling below a summer maximum of 40 degrees centigrade is not usually economical.

LOAD CYCLE

Daily load cycle is based on measured data. For practical application most loads are either industrial or residential. Only for base load stations and other special applications is it necessary to use other load cycles. For general use ratings for eight-hour and four-hour loads cover all conditions closely enough.

EMERGENCY OPERATION

The loading guide gives elaborate curves for "Short-Time Loading with Moderate Sacrifice of Life Expectancy." Acceptance of these curves is not enough. They present the user with a choice of "Loss of Life" for which he may load, and it is up to the user to justify some specific level of short-time loading before he can apply the guide to his own system.

For the substation system to which the guide is being applied, large power transformers are normally operated in parallel banks of two to five transformers. Total load per bank is limited to that which can be carried with the largest unit out of service. Replacement time for any unit with available spares is from two to five days. Maximum emergency loading will occur only during an outage of the largest unit of a bank at the time of heavy load on the group. On the basis of such infrequent occurrence, emergency short-time loading was limited by a hottest-spot copper temperature of 140 degrees centigrade for residential loads, and 135 degrees centigrade for industrial loads. According to the guide, loss of life of insulation will not exceed two per cent for each such operation.

The importance of setting the emergency limit first should not be overlooked. The ratio between emergency and normal load for this type of operation is high. For example, with three equal units in parallel, the emergency load with one unit out of service is 150 per cent of the normal load. Parallel units are frequently of different size. For about 1,000,000 kva of installed capacity in 55 substations, the average ratio of emergency load to normal load is about 150 per cent. In most cases, ratio of emergency load to normal load will be greater than the ratio of emergency capability to normal capability. When emergency load and capability are matched up, normal load will be below capability.

Load capability can be increased usually by use of auxiliary fan cooling during emergency operation. The fans used for emergency cooling are ordinary 30-inch commercial units, having a capacity of about 10,000 cubic feet per minute. They were chosen, when first used, because they were readily available, portable, and inexpensive. Tests showed that for temporary use, four such fans would give satisfactory forced-air cooling on a 7,500-kva self-cooled transformer.

For the group of substations mentioned before, increased capability in emergencies up to about 25 per cent have been obtained by use of such fans. For the 55 substations, two complete sets of fans are available for emergency use. In this way, the ratio of emergency capability to normal capability has been brought closer to the ratio of emergency load to normal load.

CONNECTED EQUIPMENT

Load ratings for direct application to existing plant or their use in design of new plant must apply as well to the connected equipment that goes with the transformers.

A large group of transformers with some as much as 40 years old presents a variety of problems. But when connected equipment in the form of circuit breakers, disconnects, instrument transformers, cables, bus, and even meters, which had been installed over the same period must be considered also, the problem is just that much greater.

For this part of the problem there is no loading guide such as that available for transformers. A firm foundation for normal and emergency operation of such equipment had to be established from all laboratory and field data that could be found in the entire industry.

OIL CIRCUIT BREAKERS

There are no established overload ratings for oil circuit breakers. Reasonably, such a device can be operated at loads higher than nameplate if it is recognized that such operation will be at higher-than-normal temperatures and may require increased maintenance. The capacity gain economically justifies such operation as an emergency measure. Emergency operation at a maximum temperature up to 100 degrees centigrade was considered acceptable.

Where circuit breakers were not frequently operated, oxidation of copper contacts necessitated derating of older circuit breakers. On newer circuit breakers with silver contacts, condition was found to remain constant even though the circuit breaker might not be operated for long periods of time.

DISCONNECTING SWITCHES

Most old disconnecting switches had low-pressure copper contacts. Also, many were installed in flashproof housings. It was necessary to derate for condition of contacts and for temperature rise within the housing. However, for rare emergency operation, temperatures on such devices were allowed to go as high as 115 degrees centigrade.

Thermal conditions on many older switches have been improved by silver-plating the contact surfaces.

INSTRUMENT TRANSFORMERS

Instrument transformers were covered by the transformer guide. In application of the guide it was necessary to make proper allowance for ambients and enclosures. The co-ordination between nameplate ratings of instrument transformers and their application ratings in metalclad switchgear is being studied now by an AIEE committee.

CONDUCTORS

Cable ratings for specific applications have long been in use in the Commonwealth Edison Company. Most of these ratings were, however, for cables installed in conduit outdoors. The problem here was to evaluate the operating conditions of cables in air, cables in fireproof compartments, and cables in every kind of an environment that 40 years of progressive substation design could create. Carrying capability of copper rod, tubing, and rectangular bars had to be evaluated in a similar manner. In every case it was necessary to establish ambient temperatures, housing factors, and temperature limitations for normal and emergency operation.

METERS

Even ammeters presented a problem. Since their scales were a function of current transformer nameplate ratings, they usually did not have a range large enough to cover emergency capabilities of the transformers. The most economic solution to the problem was to use portable, multiple-range meters for emergency operation. The same meters were designed for use on other types of system equipment also, wherever emergency loads were off-scale on standard meters.

APPLICATION

Emergency load capabilities must be applied from two different points of view, system planning and system operation.

For planning, the load capabilities are furnished in detail. The transformer is the major unit, but all limitations of connected equipment are considered. The lowest limitation becomes the rating of the transformer. Ratings for each group of transformers supplying a common load are matched up with present and future load requirements. Group capabilities can then be increased by replacing limiting equipment up to the transformer capabilities. If a transformer is replaced with one of larger capacity, only those portions of the connected equipment which would limit the new transformer need be replaced. These procedures serve to develop a co-ordinated record of all equipment on a load capability basis, rather than on a nameplate basis, for planning future transformer requirements.

For operating, capabilities of the transformers are issued twice each year, giving only the limiting capability in each case for normal and emergency operation. Indicators are placed on the ammeters for each transformer showing these limitations.

The operator uses these indicators as the guide for safe loading of the transformer and all equipment directly connected to it.

Frequently the immediate result of these load capability surveys has been a temporary decrease in rating below the nameplate of the transformer until such time as a limiting piece of connected equipment could be removed. Quite often elimination of a minor bottleneck will increase the total safe capability 20 or 30 per cent. For both system planning and operating the analysis of load capabilities serves as a complete working guide.

RESULTS

First of all, the careful analysis of load capabilities of substation transformers has resulted in increased average loading of the transformer system. In the past five years, for the million kilovolt-amperes of substation transformers, the maximum loads have increased about 30 per cent. During that time only 3.7 per cent of actual transformer capacity has been added.

In other words, our normal maximum loading has increased about 26 per cent.

Effective capacity for the same installed kilovolt-amperes has been increased by acceptance of higher emergency loading conditions, with auxiliary emergency cooling, and by elimination of bottlenecks in connected equipment to permit the over-all use of these higher transformer loads.

Comparable gains have been made in loading of power transformers in applications other than the substation group on which the primary study was made.

Distribution Transformers

MASS PRODUCTION PROBLEM

The loading of distribution transformers in a large utility system differs from the problem of loading substation transformers, as discussed in the previous section of this paper, primarily in the number of units involved. In a city the size of Chicago, for example, approximately 40,000 transformer units are involved on the distribution system. Since these transformers serve relatively small loads involving small groups of customers, or, in some cases, only one customer, various load cycles will be involved. These may range from refrigeration loads having a summer maximum with long-hour use, to decorative holiday lighting in residential areas involving use for only a few hours each day for about ten days of the year.

Although transformer characteristics will vary considerably, each unit cannot be treated individually in the loading analysis. New transformers purchased during the past ten years vary as much as 15 degrees centigrade in the average copper temperature rise at full load, and as much as 20 degrees centigrade in the copper-to-oil temperature gradient at full load. Transformers removed from the line for reinstallation elsewhere on the system show varying degrees of sludging and blocked oil ducts. Some have shown extremely high copper temperature rise on full load test.

These variations would theoretically make it desirable to have a very large number of classifications in loading practice, depending upon type of load and transformer characteristics. However, it is obvious that a practical solution requires a certain amount of uniformity in the approach to the loading problem.

BASIS OF LOADING POLICY

Several limitations enter into the determination of a desirable loading policy for distribution transformers. Obviously economics would be a major consideration if other limitations were not lower than the economic limit. As indicated in the first part of this paper, calculations based only on transformer losses and fixed charges would indicate a desirable loading well in excess of practical limits.

Voltage regulation is an important factor in this problem. In a large distribution system it is common practice to adjust voltage regulating equipment supplying 4,000-volt distribution feeders to compensate for voltage drop in the primary feeder and drop in the average-loaded distribution transformers supplied through the regulators. This means that the heavily loaded distribution transformers will have a terminal voltage lower than standard, and lightly loaded transformers will have a terminal voltage higher than standard. Since there is considerable diversity in loading cycles of various transformers, the higher the maximum loading adopted for the system, the greater will be the spread between loads on individual transformers at any time, and the greater will be the voltage range. This situation can be somewhat alleviated, but not avoided, by the use of low-impedance transformers. Another factor of importance in the consideration of maximum loading is service continuity. Obviously any approach to the loading problem which results in a relatively short life of the distribution transformer increases the failure rate of transformers in service, with a corresponding detrimental effect upon the quality of service rendered.

Consideration of the factors mentioned before has led to the adoption of the ASA "Guide for Loading Oil-Immersed Distribution and Power Transformers," as a basis for determining practical limits to be applied on the large distribution system with which the writer is associated.

APPLICATION

In the application of this Guide to distribution transformers, load cycles are classified primarily as residential (short-hour, winter maximum), commercial (medium short-hour, winter or summer maximum). and industrial (relatively long-hour use, winter or summer maximum).

The residential transformers, in general, are permitted to carry 140 per cent of nameplate rating during the normal winter maximum load period, with a special allowance of 170 per cent during the holiday season. Transformers supplying commercial and industrial lighting and small power loads are given more individual attention. Demands on these installations usually are of somewhat longer duration than for residential transformers, and are usually higher in the winter than in the summer. Although sometimes limited by summer conditions, a maximum demand, in most cases, of 125 per cent of nameplate rating is permitted. Installations with a summer maximum, and installations enclosed in vault structures where limited ventilation may result in a relatively high ambient temperature, may be restricted to a demand of 100 per cent to 110 per cent of nameplate rating. Transformers supplying industrial power load are given individual attention in most cases, with resulting permissible loads varying from 100 per cent to 125 per cent of nameplate rating, depending upon the time of maximum demand and the load cycle involved. The average installation in this class is permitted to carry a maximum load of approximately 120 per cent of nameplate rating.

At the time of installation of a transformer in any of the classifications mentioned before, the probability of future load increase is studied and a transformer installed which is believed adequate to handle the load at that installation for at least six years before replacing. Load supervision over all transformers is maintained through a periodic check of connected loads in the case of residences and small commercial customers (from card records), maximum demand information from meter records in the case of larger installations, and from a regular program of field measurements of approximately ten per cent of all transformers each year. These measurements not only provide accurate data on the immediate loading of the installation tested, but also provide basic data for estimating demands on transformers not tested.

RESULTS

The average loading reached on a large transformer system will depend upon maximum load permitted, available sizes of transformers, rate of growth, and replacement labor costs. Distribution transformer loads on radial systems are not affected as a rule by emergency ratings, as is the case for substation transformers.

At the present time, the average loading of the distribution transformers in the system referred to is estimated at 95 per cent of nameplate rating. This loading has increased gradually over the past years from approximately 73 per cent, the figure which applied in 1939 under a less severe loading policy. This increased loading represents a saving of over 400,000 kva in transformer capacity, or approximately 19 per cent in investment in transformers installed. This improvement in transformer loading and saving in investment have been effected with relatively small increase in service interruptions. Although the rate of interruptions has risen slightly since 1939, it is still well below acceptable limits. Some further increase is anticipated over a period of years, but the present margin between failure rate and satisfactory service is considered adequate to allow for this trend.

CONCLUSIONS

Present high costs of electric plant have raised the economic limits of transformer loading far beyond the practical thermal limitations of loading for a reasonable life of the equipment.

Proper application of the ASA Guide for Loading Oil-Immersed Distribution and Power Transformers[1] can raise the average loading of most transformer systems.

For daily loading it is not usually economical to load transformers for less than normal life.

For infrequent emergency use, operation with some sacrifice of normal life is justified. Where emergency and normal loading must be coordinated, use of auxiliary cooling during emergencies will permit increased emergency loads and in turn may raise the permissible normal loads.

Transformers are only part of any electrical circuit. Wherever transformers are loaded according to thermal limitations, full consideration must be given to the thermal and electrical limitations of all other parts of the circuit.

Appendix. Formulas for Curves

In Figure 1

$$A = \frac{LN^2CS + LF + RD}{NT}$$

where

A = Total annual cost of fixed charges and losses, per kilovolt-ampere

L = annual cost of losses per per cent load per kilovolt-ampere

N = economic peak load in per cent of nameplate rated full load

C = copper loss in per cent at nameplate rated full load

F = core loss in per cent of nameplate rated full load

R = rate of annual fixed charges in per cent $\times 10^{-2}$

D = installed cost per kilovolt-ampere of nameplate rated full load

S = loss factor

$= \frac{H+P^2(24-H)}{24}$ for a rectangular load cycle

T = load factor

$= \frac{H+P(24-H)}{24}$ for a rectangular load cycle

H = duration of peak load in hours

P = off-peak load in per cent of peak load $\times 10^{-2}$

In Figures 2, 3, 4, and 5

$$N = \sqrt{\frac{LF+RD}{LCS}}$$

In Figure 6

$$J = \frac{DK(\epsilon^{0.0865t} - 1)}{Rt}$$

J = justifiable installed cost per added kilovolt-ampere

K = annual depreciation charge

t = load in per cent above normal full load

Discussion

W. R. Brownlee and **J. A. Elzi** (The Commonwealth and Southern Corporation, Jackson, Mich.): So many factors enter into the economic loading of transformers that each general type of application usually will justify specific analysis. Therefore, the authors have been especially helpful in providing a series of curves showing the range of influence on economic loading of the various important elements.

The authors conclude that economic considerations, other than transformer life, would dictate loadings considerably in excess of present practices, but that the extra depreciation charges would make it uneconomical to load units beyond the point where the normal expected life begins to be reduced. This might naturally lead to speculation on the desirability of transformer designs of smaller physical size and correspondingly higher losses, but with means for more rapid heat dissipation, along the lines of some of the forced cooled varieties of transformers now available. Comparisons of such units for a specific application, such as a base load generating plant may show that the larger transformer is not necessarily the higher cost unit.

The comparison given in Table I of the discussion is based on a conservative value of

Evaluation of losses			
Capacity charge, kw	0	6,400	16,200
Energy charge, kw	0	15,360	38,880
Cost plus kw loss charges	$186,000	$188,760	$186,080
Capacity charge, kvar	0	15,000	30,000
Total comparative costs	$186,000	$203,760	$216,080

$100 per incremental kilowatt of generating capacity, an average weighted energy charge of 3 mills per kilowatt hour and on full load operation of 8,000 hours per year with operating costs capitalized at 10 per cent. In addition to the value of the kilowatt losses, account should be taken of changes in transformer reactance with reductions in physical size and corresponding increases in kilovar losses. In overhead transmission systems, especially if the generating station is in a load area, the extra kilovar loss may be evaluated at, say, $10 per kilovar. The table compares a self-cooled, forced air cooled, and forced oil-forced air cooled version of a 75,000-kva 3-phase 138-kv transformer on the basis of cost (transformer alone), evaluation of kilowatt losses and adjustment for kilovar losses.

It is seen that the first cost of the self-cooled transformer is $55,000 or 42 per cent greater than that of the forced oil-forced air cooled unit. However, with proper evaluation of the differences in kilowatt losses (including auxiliaries), there is little difference in the combined cost, and if a reasonable value is assigned to the extra kilovar losses in the smaller forced oil-forced air unit, the self-cooled transformer is $30,000 or 14 per cent lower in over-all cost than the forced oil-forced air unit. Where cooling water is required for other purposes, such as generator cooling, the application of a water-cooled transformer at a generating station may show rather startling over-all economies which will overshadow the increased operating attention which they may require.

Even in the case of this specific example of a generating unit transformer, the individual circumstances must govern, especially where 3-phase units of the larger sizes cannot be built economically except in the forced-cooled (or water-cooled) type. In view of present trends in construction costs and the costs of electric power on an integrated system, a review of basic transformer designs seems in order to provide a better economic balance of fixed and operating charges without encroaching on transformer life.

D. L. Levine and **H. E. Smith:** W. R. Brownlee and J. A. Elzi have examined the case of the base load station where the transformer carries almost a continuous steady load. They show that the higher initial cost self-cooled transformer with low operating cost has a lower annual cost than the lower priced forced-air or forced-oil cooled transformers with their higher operating costs.

This case could be examined by the methods of the paper. The transformers having forced cooling can be considered as smaller transformers operating at overloads thermally permissible because of added cooling.

Cost curves for these transformers would show that, for continuous loading, such overloads would not be economical.

Transformer Audio Noise Problems on an Electric Power System

C. S. MURRAY
ASSOCIATE AIEE

Synopsis: Since the end of the war, increased load demands, together with the location of housing developments in the vicinity of the power station, tend to make the electric power company more susceptible to noise complaints than ever before. Power companies which had not been concerned with the noise problem in the past now have become involved. The various factors of noise are covered and explained insofar as they apply to a transformer, one of the most common sources of noise. It is hoped that the review and discussion of the problems which exist may be of value to those interested in transformer noise, particularly to the transformer manufacturers and those responsible for transformer noise standards. The experience and views of others, which have been reported elsewhere, are discussed, and a list of references is given for those who care to go into the problem in more detail.

BEFORE the last war the general public was becoming noise conscious and was insistent that all types of objectionable noises be eliminated. During the war, however, the public realized that it could not conscientiously make the same demands of their power company, that had been called upon by the government to supply as much power as possible with the equipment which was available. It was realized in a number of cases, that equipment had been pressed into service that normally would have been used for standby service only. In other cases, equipment could not be removed from service in order to make improvements, or materials for making improvements were not available.

After the war, the public picked up where it had left off prior to it. However, in addition to the revived interest of the public, there are other factors which tend to make the power company more susceptible to noise complaints than at any time in the past. There was a time when generating stations and substations were located in nonresidential areas, but since the war, housing developments have been built adjacent to these stations. Because of the increased load demand, it has become necessary to increase the capacity of the existing stations. Economics demands that the additional power transformers be of the larger sizes and be installed outdoors. Then again, due to load increases, it has been found economical and sometimes necessary to locate unit substations at the load centers, which are in inhabited districts. In many cases the capacity of the power transformers for the packaged unit can create sufficient noise to make their presence in the area objectionable unless proper precautions are taken in the design of the transformer. The distribution system located in a metropolitan area also enters into the transformer noise problem. Because of the nature of the system, it is necessary to install transformers in vaults beneath the streets and in the basements of various buildings. In many of the taller buildings, vertical networks are used; the transformers are located on the upper floors, sometimes with offices on floors both above and below the transformer vaults.

One would surmise that the power company located in a metropolitan area is more concerned than any other with the noise problem. This is true, but when the foregoing factors are considered, any company with outdoor transformer installations, except those in areas remote from residential buildings, is susceptible. As the power demands increase, the transformer noise problem undoubtedly will become increasingly important.

There is very little information in the technical literature to aid the power engineer in obtaining a clear understanding of the transformer noise problem. What information there is available is scattered over many articles. Most of the literature covers the entire audio band, whereas in transformer noise problems the band usually is restricted to frequencies below 500 cycles which are multiples of the power frequency. Very little has been published concerning outdoor noises of this type. The problem is a complex one and is far removed from the problem that the sound engineer has in the laboratory or at indoor locations. It is hoped that the following material, much of which is considered in detail in the references, may be beneficial to those concerned with the problem. It is an attempt at bringing into a single article the highlights of transformer noise as it concerns the power engineer.

The Cause of Transformer Noise

It has been fairly well established that the audio noise of a transformer is caused mainly by the change in dimensions produced in the steel core when it is magnetized. This has been termed magnetostriction. The alternating magnetizing force sets the core in vibration. This vibration is transmitted with small attenuation through the oil and tank to the surrounding air. This results in the characteristic hum emitted by transformers. The amount of noise emitted and its frequency depend on the induction, magnetostriction, and nature of the iron, and on the weight and linear dimensions of the core.[1,2]

If the supply frequency is considered as 60 cycles, the frequency assumed throughout this paper, the noise emitted will have a fundamental tone of 120 cycles per second and harmonics of this frequency. In general, the outstanding noise from distribution transformers is

Reproduced from ASA Standard Number Z 24.2—1942

usually of a frequency of 120 cycles, while for the larger power transformers the outstanding noise may have a frequency of either 120 cycles or 360 cycles. Occasionally, the 240- and 480-cycle components may be outstanding. Therefore, it may be said that, in general, only that range of frequencies between 120 and 480 cycles need be considered here.

Response Characteristics of the Human Ear

Before any equipment can be designed to measure the noise, or before the noise from the transformer can be evaluated properly, we must have some knowledge concerning the characteristics of the ear. It is the ear which dictates whether a sound is objectionable; it is the final judge or arbiter.

Probably the most important aids in understanding the ear are given in ASA Noise Measurement Standard[3] in the form of curves. Figures 1 and 2 are reproductions from that standard, and the power engineer should become acquainted with them.

Figure 1 shows the equal loudness contours for pure tones. The ordinate for the curves is the intensity level, a measure of the amount of noise emitted. For these curves and in most practical sound work the unit is the decibel. The decibel is actually the measure of the ratio of two amounts of power, one being the intensity of the sound under consideration, and the other a reference intensity which, at the present time is 10^{-16} watts per square centimeter. Expressed mathematically

$$\text{Intensity Level} = 10 \log_{10} (I/I_0) \text{ decibels} \quad (1)$$

The ear responds to intensities from minute values to values 10^{12} times as much. The use of decibels provides a practical scale to cover the enormous range. It will be noted that increasing the intensity 10 times results in a change of 10 decibels; doubling the intensity results in a change of 3 decibels. An inspection of the contours shows that the response of the ear depends both on intensity level and frequency of the tone. All pure tones having intensity levels and frequencies on the same contour are equally loud. A 360-cycle note having an intensity level of only 54 decibels is just as loud as a 120-cycle note having an intensity level of 65 decibels, both being on the *50* contour. Both of these tones have a loudness level of 50 phons. The loudness level in phons (phons to distinguish from decibels) of a sound is equal to the intensity level in decibels of the equally loud 1,000-cycle-per-second tone. For these contours various tones were compared with the equally loud 1,000-cycle tone used as a reference.

Figure 2 shows the loudness as a function of loudness level. The loudness scale is such that the ratio of any two loudness values indicates the relative loudness between two tones. For example, a tone having a loudness of 8,000 loudness units is twice as loud as one having 4,000 loudness units.

The use of the two curves gives us a means of determining how much louder one noise is than another. Knowing the intensity level and frequencies of both noises, we can obtain their loudness levels from Figure 1 and their relative loudness from Figure 2.

Figures 1 and 2 are based on pure tones and are obtained under conditions where the background noise or ambient noise is small so as not to interfere with the pure tone heard by the members of the sound jury, who used their ears in the determination of the curves. The presence of other tones would alter the curves, since these other tones might mask (raise the threshold of hearing for a tone to some higher value) the tone under study. Investigations have been carried out whereby the curves may be used for complex tones, that is, those of more than one frequency.[4]

Objective and Subjective Principles of Noise Measurement

The objective principle of noise measurement is employed generally in transformer-noise measurements in the United States. The sound level meter is based on this principle of measurement and is discussed below. In order to evaluate the noise from a transformer, one must understand the limitations of his equipment for measuring that noise.

Obviously, the ideal noise measuring instrument would be one in which a single meter would indicate the loudness of a noise of any type in terms of a primary standard. In order to design this meter, the response of the ear would have to be known, not only for pure tones as given in Figure 1, but also for any complex sound such as that emitted by a transformer. The response of the ear to complex sounds is still in the experimental stage, although methods have been advanced for calculating the loudness of complex sounds.[4]

The subjective or aural comparison method of noise measurement, consists of comparing the noise under measurement with an equally loud reference tone, either pure or complex. For example, the noise under study may be listened to with one ear and the reference tone listened to with the other. The reference tone is adjusted until it is equally loud to the noise under study. It will be noted that the relative loudness could be determined for any sound no matter how complex. It also will be noted that the human element would play a big part in the values obtained. Manufacturers of noise meters in the United States have concentrated on the objective noise meter.

The objective principle consists in having a meter with a response based on the equal loudness contours given in Figure 1. When a pure tone of any frequency is being measured, and assuming the meter is equipped with means to follow all the equal loudness contours of the ear, the meter will indicate the equivalent 1,000-cycle-per-second value. This type of meter, equipped with all the equal loudness contours given in Figure 1, can be used to obtain the loudness of a pure tone. However, when a complex sound is being measured, the meter operates to sum up the energy in the equivalent 1,000-cycle values and indicates this energy sum in a decibel value. This assumes that a given pure tone of the complex sound will be just as loud regardless of the presence of other tones. Measurements made by various investigators show that the ear is not responsive to an equivalent energy summation.[4,5] In the case of transformer noise the summed equivalent energy sometimes is practically equal to the energy of the largest component. The objective meter would indicate a value practically equal to that of the largest component. However, the investigators[4,5] show that the presence of harmonics might make the noise much louder, even though its contribution to the total equivalent energy is negligible. In one case,[5] in tests on ring cores of transformer steel, the objective meter indicated a loudness level of 58 phons and the subjective meter a value of 87 phons. Referring to Figure 2 it will be noted that the objective meter indicated a value about 1/8 as loud as actually existed. Many have found, however, that the objective meter indicates values only a few decibels below the subjective method for sounds not predominantly harmonic in character.[5,10] The American Standards recognize that the loudness level indications may be in error.[6] The sound level meter based on the objective principle has been a useful tool for transformer noise measurements and is recognized as the best means, to date, for obtaining a quantitative noise measurement. Its limitations and the assumptions based on its indications should be kept in mind.

The Sound Level Meter

Commercial sound level meters are not equipped with all the equal loudness contours given in Figure 1. Most of the available sound level meters are equipped with three scales, one approximating the *40* equal-loudness contour, another the *70* equal-loudness contour; the third has a "flat" responsive characteristic. The meter, with its weighted scales (*40* and *70*), is the result of an attempt to duplicate the action of the ear for complex sounds in a practical manner. The response and tolerances for sound level meters have been specified by the American Standards Association.[6]

The sound level meter indicates the sound level of the total noise, a frequency analyzer being necessary for measurement of the components of the noise.

The question often arises as to which scale or weighting network should be used for a particular noise measurement. A chart showing the loudness that would be indicated by each of the three scales for various intensity levels as compared to the loudness as would be interpreted by the ear is given in Figure 3. Pure tones of the frequencies most often met with in transformer audio-noise measurements are given. A 1,000-cycle tone also is given for comparison and shows that the scales all indicate the same value for this frequency. The charts are based on Figures 1 and 2 and the design objective of the ASA Standard for Sound Level Meters.[6] If it is desired to obtain a measurement of the noise that will approximate the loudness indicated by the human ear, the chart will indicate which scale should be used. For instance, the chart shows that for an emitted noise (intensity level) of 80 decibels, having a frequency of 120 cycles, the 70-decibel scale should be used. In transformer audio noise measurements the 40-decibel scale usually is specified regardless of intensity level or frequency. This practice is discussed later.

Experience with various sound level meters of different manufacture while being used in making sound level measurements on transformers shows that certain precautions and procedures must be followed. It should be borne in mind that nearly all transformer noise measurements on an electric power system are made outdoors. Ambient temperatures, stray fields, and varying ambient sound levels (background noise) offer problems not met in laboratory measurements.

It has been found that low temperatures affect the microphone, especially if it is a crystal type, and the meter itself. In tests at temperatures near freezing, with battery operated meter and a crystal microphone, the value of sound level may be in the order of 10 decibels below the value it would indicate at normal room temperature. The major part of this difference is attributed to the crystal microphone. This experience indicates the necessity of using a standard source of sound for over-all calibration of the microphone and meter. It is an accepted practice by many not to make any measurements until after the equipment, both meter and microphone, has been exposed to the existing temperatures for an hour or so.

It also has been found that most sound level meters are not sufficiently shielded against stray fields that may exist in the field. The crystal microphone generally is not affected, but experience with dynamic microphones of the moving-coil type shows that large errors may result from stray magnetic fields. Usually any effect on the equipment can be detected by orienting and moving it with respect to the field. Generally, the meter is placed at some distance from the transformer, the microphone being connected to the meter through shielded leads.

Ambient sound levels of high intensity and varying magnitude exist during the day; this usually demands that the sound level measurements be made during the early morning hours. Sound level measurements should be made when the ambient sound level (sound level when the transformer noise is turned off) is at least 10 decibels below the transformer noise.[7,8] There are methods of correcting for the transformer sound levels if the 10-decibel difference cannot be attained.[8,9] Even when measurements are made at night, street traffic, whistles, trains, chirping of birds, and many other noises interrupt the measurement. There also is another reason for making tests during the early morning hours, especially when measurements at locations remote from the transformer are desired. It is during this period that the transformer noise is most audible and the likely time when this noise will be most objectionable.

Experience shows that the use of the sound level meter by itself is not sufficient in most measurements made at locations remote from the transformer. The sound analyzer used in conjunction with the sound level meter is almost a necessity, in order to evaluate the noise. Many times tests are made to detect the magnitude of improvements made to eliminate objectionable noise. The improvement often does not show up in the indication of the total noise value but in the value of the component frequency only.

Tests often are made to check the measurements made by others. The ASA response characteristics[6] allow a tolerance for sound level meters such that two different meters could indicate values differing by 5 decibels for a noise having a frequency of 120 cycles. This is a considerable difference when it is kept in mind that two equal sources of noise when sounded together will only produce a sound level value of 3 decibels above that value when either is sounded alone. Many users have their meters calibrated by a standardizing sound laboratory to obtain the correction that must be applied to their meter to place its indications at the "design objective."

Objectionable Noise

The problem of determining whether a noise is objectionable is a complex one. A noise which is loud may not be objectionable, although there are many who feel that until the limit of objectionable noise is arrived at, loudness should be the criterion. A noise that is objectionable in one case may not be objectionable in another. The existing ambient noise plays a large part in this determination. In general, unpitched noises, that is, noises which do not have any particular component frequencies, are not objectionable if from 15 to 20 decibels below the total noise at the location considered. Masking of these noises by the existing ambient noise may make them unnoticeable. Pitched noises, those having a single outstanding frequency, are extremely objectionable, and it may be necessary for them to be more than 20 decibels below the total noise in order not to be objectionable.

Noises of the higher frequencies are more objectionable than equally loud low-frequency noises. Noise which is varying continually in intensity or frequency is particularly objectionable. There have been low-frequency noises, caused by extremely large objects in vibration, which were barely audible but gave a feeling of uneasiness. There are no definite ranges of sound levels and frequencies to define an objectionable noise. The power engineer must use experience to estimate whether the noise emitted by his transformer is objectionable.

Transformer Noise Standards

The National Electrical Manufacturers Association Standards for Transformers[7] specify the procedure for obtaining the "average" sound level of a transformer. These standards also specify the average

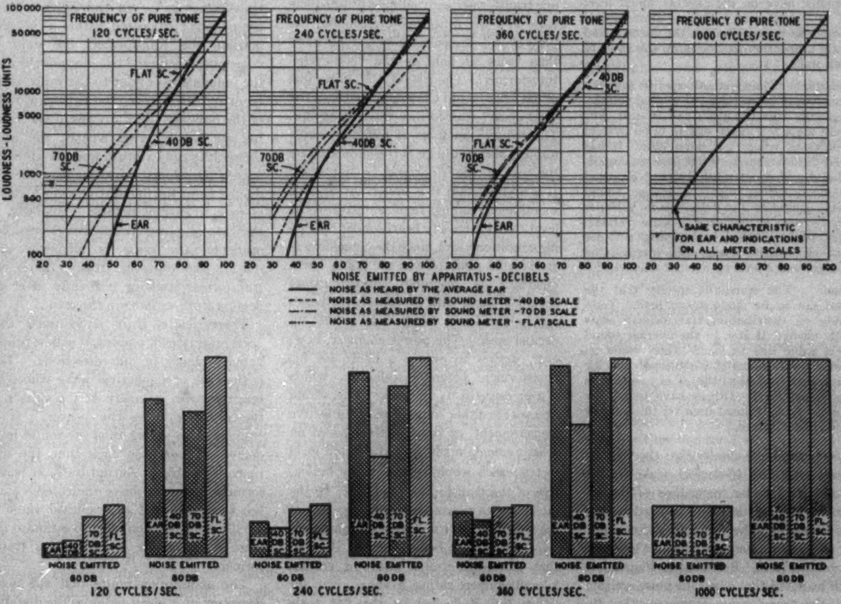

Figure 3. Comparison of sound level meter scales with the human ear for different pure tones

(Above) Apparatus noise measurement; (below) direct comparison of loudness sound level values of the total noise that distribution and power transformers should not exceed.

Briefly, the average sound level value is determined by averaging the readings obtained at a number of points around the transformer, at specified heights and at a distance of one foot from the major sound-producing surfaces. There are other specified conditions of making the tests, and the power engineer may not be able to comply with some of them. He is then left with the problem of determining what effect these conditions have on any measurements he may make.

Some of the conditions are as follows:

Location of Transformer. The standards specify that the transformer be located so that there is no acoustically reflecting surface, other than the floor or ground, within 10 feet of the transformer. This presents no problem where distribution transformers are concerned, since they could be removed to the laboratory where a supply is available to energize them. However, with power transformers, the manufacturer himself may find it difficult to obtain an adequate supply and space for factory tests. Once installed, the transformer is separated from other electric apparatus by means of fire walls. There is very little information as to what effect the fire walls, which are acoustically reflecting surfaces and less than 10 feet from the transformers, have on the average sound level of a transformer. Power transformers should be noise-tested at the factory and again at location to determine the effect of such walls.

Voltage. The standards specify that the transformer be energized at normal voltage. Generally this condition can be met, but there are a few cases, due to other system conditions, when it is impossible. It has been found from tests on 3-phase liquid-filled distribution transformers of 500- and 1,000-kva rating, that the average sound level changes by 2 to 3 decibels for a 10 per cent change in balanced 3-phase voltage. Tests made by others indicate that a 10 per cent increase in voltage will increase the average sound level by about 2 decibels.[10,11]

Load. The standards specify that the tests are to be made at no load. Tests made on distribution transformers show little change, if any, in the average sound level value due to load. Tests made on power transformers of 60,000-kva capacity show that load has little, if any, effect on the sound level. Others have found the same.[12,13] Additional data on this subject should be obtained.

The standards specify that the tests be made with the 40-decibel scale on the sound level meter, regardless of the intensity level of the noise emitted by the transformer. The component frequency or frequencies, loudness level, or loudness is not specified. Referring to Figure 3 it will be noted that when the noise emitted by the transformer increases, the 40-decibel scale ceases to give an approximate picture of the loudness, and that either the 70-decibel or the flat scale would indicate the loudness better for the higher intensity levels.

In general, distribution transformers of 500- and 1,000-kva rating emit noise of such values on the 40-decibel scale as to approximate loudness level. However, above a given kilovolt-ampere rating, the amount of noise emitted is of such a value that the 40-decibel scale indicates a value much below the loudness level. For example, the NEMA standards specify a sound level of 80 decibels for a 50,000-kva transformer. Assuming the noise emitted has a frequency of 120 cycles, this is equivalent to an intensity level of 96 decibels. The loudness level in phons indicated by Figure 1 would be about 96. Referring to Figure 2 and comparing loudness units for 80 and 96, it will be noted that the transformer actually will be over three times louder than indicated by the meters. Others have pointed this out too.[13] Looking into the matter further, and still considering the 50,000-kva transformer above, the standards specify 80 decibels sound level.[9] Two manufacturers could each supply a transformer having an average sound level of 80 decibels on the 40-decibel scale. Yet if one transformer emitted mostly 120-cycle noise and the other 360-cycle noise, the "120-cycle" transformer would be more than twice as loud as the "360-cycle" transformer. The use of the 70-decibel or flat scale would have indicated that the "120-cycle" transformer was the louder. The relative loudness of different transformers also would be better indicated by the use of the 70-decibel or flat scale. It is argued[8] that it is important to have sound level readings representative of the level that is actually heard under operating conditions, and, since the transformers are located remote from the point where quietness is desirable, measurements should be made with the scale corresponding to the lower level, that is the 40-decibel scale. The power engineer, however, desires to obtain a figure for his transformer, before installation, which is a measure of its loudness. This would necessitate either some form of subjective measurement, or some method based on measurements made with the sound level meter which would offer a value indicative of the transformer loudness. In the interim, with measurements being made at the 1-foot distance and with a single sound level meter value being specified, it is felt that for transformers above a certain kilovolt-ampere rating, a value given for either the 70-decibel or the flat scale would be more indicative of the transformer loudness than a value for the 40-decibel scale. The matter should be reviewed by those responsible for transformer audio noise standards.

Tests have been made on a 60,000-kva transformer having an average sound level closely approximating that specified by the National Electrical Manufacturers' Association. The 360-cycle component of the transformer noise, at a point 1,400 feet distant, was about 5 decibels below the total noise at that point. The transformer noise was audible and in the objectionable range. Power transformers supplied in accordance with the National Electrical Manufacturers' Association recommended sound levels have caused and will cause, in many cases, noise complaints. It is felt that a more realistic approach to this problem is required on the part of the manufacturers and bodies responsible for standardization of sound levels.

Transformer Noise at Locations Remote from a Transformer

The noise reaching an observer who is located remote from the transformer is either air-borne or transmitted to him through rigid connections joined to the transformer case. In the latter case, if the observer is located within a building housing the transformer, the noise is transmitted from the transformer through the foundation or floor to the walls of the room and thence over the structural work of the building. If the walls of the housing are not of great weight, the walls themselves may vibrate and set up other noises. Outdoors, the noise may be conducted from the foundation over a strata of rock to distant points. Generally, in the case of power transformers installed outdoors, the noise is air-borne and reaches the observer directly from the transformer itself or indirectly after reflection from surfaces in the area.

Theoretically, if it is assumed that noise originates at a point, it will be propagated radially in all directions. This is the case of a spherical wave whose intensity varies inversely as the square of the distance from the source. It is equivalent to saying that the sound level decreases 6 decibels each time the distance is doubled. Actual tests on transformers in service have indicated values less than this, and an empirical value of 4.5 decibels has been used to estimate the noise at a remote point from a transformer.

The assumption made that the noise decreases at a given value as the distance from the source is increased does not hold if the phenomenon known as interference exists. Sound waves of the same frequency are emitted from different areas, resulting in the effects of the individual waves adding at some points and subtracting at others. In this case, for a range of distances from the transformer, the intensity of the sound goes through a series of maximum and minimum before reaching a distance where the intensity decreases as indicated without interference. The indirect sound from reflecting surfaces such as nearby walls or ground will interfere with the direct noise. The indirect noise may come from some other area of the transformer itself, especially if the dimensions of the source are large compared to the wave length of the sound, which might be the case. Interference may be set up by noises from adjacent transformers. Tests have been made by others[14] which show that the transformer noise at 150 feet from the transformer was as much as the noise 10 feet away; at certain points remote from the source, the transformer noise was more than at positions much closer.

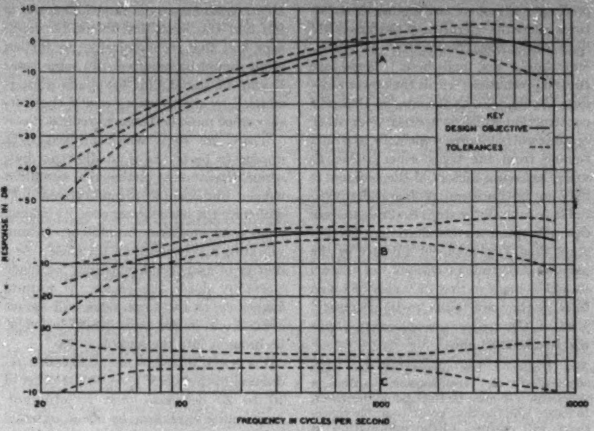

Figure 4. Over-all free-field response-frequency characteristics and tolerances for sound level meters

Reproduced from ASA Standard Number Z 24.3—1944

When measurements are made at the transformer within one foot of the case, the indication of the sound level meter, which is the total noise, remains fairly steady at any one point, assuming that the ambient sound level is at least 10 decibels less than the transformer noise. At any one point there may be a variation of the individual components, depending on the frequency of the component being measured, physical size of the transformer, and nearby reflecting surfaces. At some remote point, assuming that the ambient noise remains at a fixed level, the indication of the sound level meter varies over a small range, usually not more than 1 or 2 decibels. However, the variation of the individual components of the noise may be considerable. The variation is caused by slight variations in the system frequency, variations of wind velocity and direction, and any movement in space of large reflecting areas, such as trucks or trains. Any of these variations may change the existing wave pattern. The amount of observed variation depends considerably on the wave length of the component being measured and the sharpness of the tuning of the sound analyzer. Generally, the components are measured over a period to note the variation and to arrive at minimum, maximum, and average values. It is the maximum transformer noise which exists over a period with which we are concerned. The human element plays a big part when using indicating instruments. Some prefer a recording of the various component noises on a chart. It would be necessary, then, to mark the chart during those periods when extraneous noises occur in the vicinity.

For large power transformers the components of the noise from point to point around the periphery of the transformer differ in magnitude and in relative value with respect to each other. To obtain the average sound level of a given component would necessitate measurement of it in the same manner as when determining the average total sound level. Generally, when the components of a transformer are desired, the noise at some distance from the transformer is analyzed.

Distribution Transformer

When the average sound level of a distribution transformer is desired, sound level measurements must be made even though data are available on a similar one. The results of sound level measurements, made on 25 transformers of different manufacture, show that the average sound level may differ by 15 decibels. Transformers of the same type and manufacture may differ by as much as 6 decibels, a variation which can be the difference between a noisy and a quiet transformer.

In general, when complaints arise from transformers located beneath the streets, the complaint is due to air-borne noise. If a complaint arises from a transformer installed in the basement or other floor of a building housing the complainant, the complaint may be due to either or both air-borne noise and noise transmitted through the floor and other structure of the building. When the latter is the cause, improvements can be obtained by placing vibration dampeners beneath the transformer and between any cable hangers and the transformer connections. There should be no rigid connection between the transformer and the structure of the building. The application of sound absorbing material to the vault walls and ceiling to decrease the noise due to multiple reflections is seldom found to be necessary. Every reasonable precaution should be taken to prevent installation of a noisy transformer in a quiet neighborhood.

Power Transformers

When large power transformers are to be installed in areas adjacent to which are residences, the noise emitted by the transformer may prove costly unless proper consideration is given to this problem as early as the purchase stage.

The transformer manufacturers should be made acquainted with the problem at hand and impressed with the fact that quiet transformers are necessary. This means that noise must be considered in the design stage, since it is practically impossible to decrease the noise level of the equipment itself once it has been built. Consideration also must be given to the design of any fans that may be used for cooling, since there are known installations where the operation of the fans could have caused noise complaints. The problem should not end here. There are certain precautions which the power engineer should take at the site, so that any construction which is necessary for other reasons will not increase the noise at points remote from the transformer. Due to many unknown factors of the problem it may not be considered economically justifiable to take all the steps that might seem desirable prior to installation. Certain steps should be taken in advance of the installation, and provisions for others should be made so that they may be taken later, if they are found to be necessary. Two of the major precautionary items will be discussed now.

Fire Walls. The placing of fire walls adjacent to the transformer is often a necessity. It may be impossible, however, to locate walls so that no undesirable reflections will result. Little information is available which shows the effect of such walls on the noise. Tests made at the factory, with the transformer located at least 10 feet from the nearest reflecting surface, and again after installation with the walls in place, will afford some information. Such a procedure would require data for a considerable number of cases; years might be required to obtain it. There is a possibility that small scale models can be used to study the subject in general, so that the power engineer could obtain a clearer understanding of the subject.

In some instances the application of sound-absorbent materials on the side of the walls facing the transformer has been considered as a means of decreasing the reflection of the noise from them. Unfortunately, there are no known absorbent materials that are suitable for outdoor use which have good absorption coefficients for the 120- to 360-cycle frequency range. Recently, in Denmark, Helmholtz resonators were built into the interior walls of various buildings, resulting in good absorption coefficients for the lower frequencies.[16] In one case, the resonators were made up of regular enclosures in the brick walls together with special tiles with circular openings. At present there are no known similar installations in this country. The possibilities of applying the idea here should be considered by those concerned with sound-absorbent materials and methods.

Transformer Foundation. Placing the transformer on a foundation on which adjacent walls also are mounted is not good practice, because vibrations from the transformer may be transmitted through the foundation to the walls and thus set them in vibration, increasing the noise. There is a possibility that the transformer foundation may rest on a strata of rock running beneath the foundation to a nearby residence. In this case, and for other similar conditions, it might be found necessary to plan on placing the transformer on cork, rubber pads, or other resilient mounting.

Let us assume that the transformer has been installed outdoors and that reasonable precautions have been taken. It is felt that this is all that should be necessary and that, economically, no further steps should be required. In some cases it may be found that too much noise is emitted by the transformer and that further steps must be taken to reduce it.

There are steps which at first sight appear to be in the right direction but, when tried, may make the condition worse. For example, it would appear that stiffening the transformer case, by adding angle or channel iron, would keep it from vibrating and thus reduce the noise. As a matter of fact, conditions may be made worse by doing this, since the natural frequency of the tank sides will be increased and noises, once inaudible, might be brought into the audible range.

For some installations appreciable reduction in the sound level, in the order of 10 to 20 decibels, must be obtained. Appreciable reduction, by means external to the transformer, has been obtained in each of the following methods:

Barriers. The method of placing a simple wall between the source of sound, the transformer, and the point where quietness is desirable, has possibilities and should be considered. The reduction immediately behind the wall is great, but the magnitude of the improvement falls off as the distance increases because of diffusion of the sound around the edges. In general, the results obtained from a simple wall have been disappointing, but there are cases where this wall was effective in decreasing the amount of noise that was being reflected towards a residence by another wall behind the transformer. Care should be exercised in placing the wall so that it will not reflect noise in another direction equally important as the direction under immediate consideration.

It often has been said that a simple wall would never be as effective as it would be if it were one side of a total enclosure. To increase its effectiveness, the wall should be extended at right angles to itself on either or both ends so as to cut down the diffusion. The attenuation of the sound due to a barrier depends on a number of factors such as the effective height of the barrier above the line joining the source of sound and the point of desired quietness, wavelength of the sound, distance between the wall and the sound source, and distance from the barrier to the point of desired quietness. The effect of walls used as sound barriers may be an expensive cut-and-try method, unless the barrier walls can be used later as part of a total enclosure if this is found to be necessary.

Tests already made using small scale models to study a particular outdoor transformer installation show that barriers properly placed will offer substantial noise reduction in a particular direction from the sound source. If the surfaces of the barriers facing the transformer can be made sound absorbing, further reduction is possible.

Total Enclosure. This method usually is considered as the last resort. The power engineer now finds himself at a point where he must house his transformer whether he wishes to or not.

In some instances, notably in England,[15] the radiators have been separated from the tank and the tank enclosed in a sound-proof enclosure. Reductions up to 30 phons have been obtained, and it is claimed that up to 50 phons reduction is possible. The transformer tank is insulated from the floor by mounting it on suitable cork or rubber blocks. All rigid connections between the tank and radiators were avoided so that vibrations of the tank would not be transmitted to the radiators, although some question the necessity for doing this. In order for a surface to radiate sound efficiently, its dimensions must be large compared to the wave length of the sound to be radiated. Most of the noise emitted by a transformer is radiated from the transformer tank. In the case of the larger power transformers, it often is not possible to enclose the tank only, and housing of both the tank and the radiators becomes necessary. Means must be provided for additional cooling, entrance of transformer connections, and removal of transformer in case of failure. Any necessary openings, such as doors and cooling-air ductwork, should be located on the side of the enclosure away from the residences, if possible. It is the soundproofing of these openings which limits the possible value of noise reduction. The walls of the enclosure, if of single-wall construction, must resist vibration, which means that they must have great weight. High efficiency without great weight can be obtained with double-wall enclosure, but bracing of these walls may become a problem in walls of large dimensions.

Any time a transformer is enclosed in a room, reflection of the sound due to the walls, ceiling, and floor increases the sound level measured around the transformer. A 75,000-kva transformer was installed within a brick enclosure in England.[13] The enclosure was designed to give a noise reduction of 45 to 50 phons. The average sound level, at one meter, was measured at the factory and found to be 79 phons, yet after installation in the enclosure, the average sound level was 96 phons. This build-up of noise amounted to 17 phons; if full benefit of the enclosure had been desired, reflection would have had to be minimized within the enclosure by application of sound-absorbing materials to the interior walls and ceiling.

Summary

1. Increased power demands and the location of housing adjacent to power stations and substations are factors which make the transformer noise problem more important than in the past.

2. The measurement of outdoor noise offers problems which do not exist in the laboratory.

3. Present transformer audio noise standards are not adequate, especially for power transformers. An average sound level value obtained at a distance of one foot from the transformer and using the 40-decibel scale of the sound level meter is not indicative of the transformer loud-

ness. Until an improved method can be devised, the use of either the 70-decibel or the flat scale is suggested.

4. Noise reduction by means external to the transformer is costly. The necessity for doing so should be avoided.

5. Power transformers built with sound levels in accordance with existing NEMA standards emit too much noise and they have caused and will cause complaints. The situation is critical; it is felt that more realistic standards are needed. The manufacturers and bodies responsible for the noise standards should co-operate toward this end.

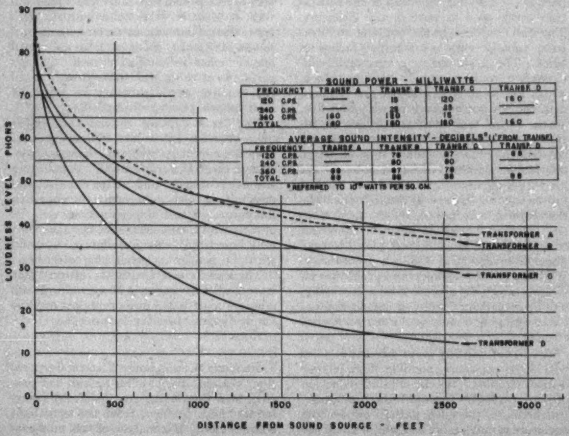
Discussion

E. A. Blomqvist (Consolidated Edison Company of New York Inc., New York, N. Y.): In Figure 1 of Mr. Murray's paper he showed the relationship between sound intensity, loudness level, and frequency. Briefly, these curves show that at low levels of sound intensity, the ear becomes insensitive to low frequency sounds. Due to this characteristic of the ear, all transformers emitting the same amount of sound power may not be equally noisy, depending upon the frequency distribution of the sound.

Perhaps the simplest way to see the effect of the frequency distribution of the sound is to take a few examples of noisy equipment with various frequency distributions and see how noisy they will sound to the ear. For this purpose, four transformers have been assumed, each emitting 160 milliwatts of sound power, but having different frequency distributions. In Figure 1 of the discussion, the loudness level in phons is plotted as a function of distance from the transformer for these transformers. The frequency components of the sound from each transformer are indicated. It will be seen that, right next to the transformers, the loudness level in phons is 85 to 88 for all units, and they will sound equally noisy. As we move away from the transformers, the loudness level decreases, and at a distance of 1,000 feet, transformers *A* and *B* produce loudness levels of about 47 phons, transformer *C* produces 41 phons and transformer *D* produces only 25 phons. Thus there is a very considerable difference in the "noiseness" of these transformers except immediately adjacent to the transformers (where it is unlikely that any one would be living).



SOUND POWER - MILLIWATTS

TOTAL	88	88	88	88

*REFERRED TO 10^{-16} WATTS PER SQ. CM.

Figure 1. Loudness level versus distance for transformers with various frequency characteristics

Looking at it another way, the number of feet away from the transformers that it is necessary to go before the loudness level drops to 40 phons is as follows: transformer *A*, 2,150; transformer *B*, 1,900; transformer *C*, 1,100; and transformer *D*, 450. This shows a very great difference. The level of 40 phons was selected for this comparison merely because it approximates the loudness level in residential areas.

These curves suggest a further method of obtaining quieter transformers in addition to reducing the total sound power to a minimum, and that is by throwing the sound power into the low frequency range. Thus, a transformer designed for a minimum amount of sound power can be further improved if that sound power can be made predominantly 120 cycles.

A. P. Fugill (The Detroit Edison Company, Detroit, Mich.): This paper by Mr. Murray is most timely, and should be of vital interest to all of us in the electrical industry. Noise reduction in all its phases has had to take a back seat during the last few years, but the time has certainly arrived when we must consider it again whether we want to or not.

To those of us who had something to do with the drafting of the original noise standards, there is a familiar ring to Mr. Murray's perfectly valid objections. When the various standards were first adopted, they were recognized as being far from perfect, as indicated by the several revisions which have already been made, but they represented the best compromise obtainable at the time. About 1930, when we at Detroit Edison first became actively interested in reducing transformer noise at our residential substations, there were no accepted methods of measuring transformer noise. Several reference levels were being used; the units in which results were expressed depended on the individual doing the work; there was no complete agreement on the response of the human ear; and the noise meter was usually designed, built, and calibrated in the laboratory responsible for the measurement. If noise limits were included in purchase specifications, they were so general as to be meaningless. Most users have little, if any, idea of how quiet a transformer should be to prevent complaints. In a word, there was almost no common ground on which manufacturer and user could get together to discuss transformer noise. Today, with our existing standards, at least, we can all talk the same language. We have measuring equipment, which, despite its limitations, does a good practical job of classifying transformers as to noise. The transformer designers have sufficient factual data to predict, with fair accuracy, the degree of quietness to be expected in a transformer before it is actually built and measured. And the user has a much better idea of what he needs to prevent noise complaints. Though we have accomplished a lot in the last 20 years, we must not be complacent and close our eyes to improvement. The points which Mr. Murray has raised about measuring equipment and methods of measurement should certainly be given very careful consideration.

Mr. Murray's contention that the present permissible sound levels for transformers are too high deserves considerable discussion. From the application viewpoint, we agree that quieter transformers are desirable. Any power transformer, 1,000 kva and above, which just falls within the present standards, may result in complaints if located outdoors in a residential neighborhood, particularly if there are several banks at the same location. Again, however, when these values were originally accepted, they were the best compromise between what the manufacturers were willing to accept, without appreciable cost increase, and what the user would like. At that time, many of the transformers we were buying were falling considerably below the limits. With the growing public consciousness of noise, improved materials and construction methods, and more attention by both manufacturer and the user to the subject of noise, we had a secret hope that these limits could be lowered as time went on without undue hardship on anyone. That has not been the case. The war intervened, and in its wake came the stress for more production in the face of material shortages and increasing labor costs. The result was that the average power transformer today is noisier than its counterpart was just before the war. In fact, particularly in the sizes from 1,000 to 4,000 kva, we have received some transformers recently which measured so far above the present specification values that we were forced to reject them. The majority of power transformers of all sizes which we are receiving currently are just about meeting the present exceedingly liberal specification values or even exceeding them slightly.

The answer, however, is not to reduce the limits arbitrarily by 5 or 10 decibels. It is quite likely that would result in an increase in transformer cost for the whole industry. There are still many transformer applications where noise is no problem and if these cases constitute a large percentage of the total transformer business, it would not be wise to raise the cost of all transformers to meet the requirements of a few applications. On the other hand, if the limits can be lowered a certain amount without appreciable increase in cost, and we are not sure that is impossible, it should most certainly be done.

Our present solution to the problem of reducing noise in residential areas where some of our distribution substations are located may be of interest. The transformers involved are rated 6,000 to 15,000 kva, with a specification noise limit of around 70 decibels. We know from experience that a 70-decibel transformer located outdoors in this kind of neighborhood may result in noise complaints. If we buy a 60-decibel transformer, and this can be done without an unreasonable increase in cost, there is a fair chance that we may still have complaints because the noise is still distinctly audible at an adjacent residence, particularly in the middle of the night. With a 50-decibel transformer, which might be built in this rating, but certainly would be expensive, we have very little chance of receiving complaints, unless the noise pattern built up by several units and various reflective surfaces happens to give a noisy spot on the adjoining premises. With a 40-decibel transformer, which probably could not even be obtained in this rating, we would be perfectly safe.

With these facts in mind, we have decided that the best solution is to buy the quietest transformer we can get without an increase in cost, and then enclose it on all sides by a wall about the height of the transformer. In our present design of this type of distribution substation, the enclosure is an integral part of the building, one wall of the substation being used as part of the enclosure. The wall conforms to the building architecture, usually with an external facing of brick. The inside surface is a reasonably inexpensive rough-textured, building block, which has some absorption at low frequencies, though not as much as we would like. There is no roof over the enclosure, although we are using a screen cover for safety reasons. We have not found it necessary to provide mechanical ventilation to move the air within enclosure. Originally we bricked up the opening in the wall through which the transformer was moved, on the basis that the transformer would be changed so infrequently that we could well afford to take down this section of wall when necessary. We are now developing a removable panel, which, though not quite as good acoustically, will be satisfactory and will make the process of changing out a transformer somewhat cheaper.

We do not find any great increase in noise within the enclosure, possibly three or four decibels at most. We can obtain a reduction of 20 decibels through the enclosure. Furthermore, the noise pattern outside the enclosure is much more uniform, with all the local noisy spots eliminated. Considerable noise does go over the top of the wall, but this is dissipated by the time it reaches the level where it may cause annoyance. Possibly, if there were a large apartment building adjacent to the substation, extra precautions would have to be taken. In addition to the acoustical advantages of the enclosures, the appearance is improved and the danger of interference with equipment reduced.

Our success with the transformer enclosure does not mean that we have lost all interest in quiet transformers. Even with the enclosure, we would like a transformer which measures about 60 decibels and a 70-decibel transformer is about the limit which we could tolerate with this arrangement.

In conclusion we would suggest that this whole noise problem be given industry-wide consideration. Perhaps this is the time for a co-operative effort sponsored by the electrical societies, to determine the best way to reduce the effect of noise, not only from transformers but from all electric equipment. The problem cannot be solved by any one section of the industry but must be viewed from all angles.

J. Q. Wray, Jr. (Pennsylvania Water and Power Company, Baltimore, Md.): Mr. Murray is to be congratulated for making available to the industry such a complete analysis of transformer audio noise. This problem will increase in importance as more installations are required in congested areas.

His paper aptly points out the difficulties encountered in eliminating objectionable transformer noise once the transformer is installed. The only really effective method of cutting down appreciable noise is to build a soundproofing wall or enclosure. Such construction is expensive and for large power transformers, will prove impractical more often than not.

In the case of a new installation, the engineer will usually have some selection as to location, and he can also take precautionary measures toward minimizing noise by the several methods mentioned in the paper. However, the man who must find a practical way of lessening the noise emitted from transformers already in service has a real job on his hands. Each job is an individual one and must be handled as such. The experiences of those who have already faced the problem would probably be helpful if such information was compiled.

The final solution to the transformer noise problem is, as Mr. Murray says, to keep the noise to a minimum during the design of the transformer itself. It occurs to the writer that in addition to the electrical design being such as to reduce the noise to a minimum, considerable reduction could be obtained by the development of an acoustic tank liner suitable for installation in oil and with the proper dielectric characteristics.

The writer concurs with Mr. Murray that more realistic standards of noise levels are required and that a more practical method for measuring these levels is needed.

S. Bennon (Westinghouse Electric Corporation, Sharon, Pa.): The author has presented an interesting survey of the transformer noise problem from the operator's point of view. His analysis of field measurement techniques and available methods of noise reduction external to the transformer provides a valuable complement to earlier

Institute papers[1,2] analyzing the problems of internal noise reduction in transformers.

Recognition of the importance of the transformer noise problem has led to a determined effort on the part of manufacturers to reduce over-all transformer levels. A significant step in this direction has been the elimination of resonances[1] which may raise the basic level of the core. The basic sound level produced by a core of fixed material and dimensions is determined primarily by its operating induction. Mr. Murray's figure, which agrees with our experience, shows that a 10 per cent change in induction will produce a sound level change between 2 and 3 decibels. Because of this relatively slow change it is apparent that a large expense is involved in any major sound level reduction secured by a reduction in the operating induction alone. On the other hand, external noise reduction secured by barriers of varying degrees of completeness, as described by Mr. Murray, also represent additional investment to achieve desired results. Under these conditions the practical solution, when unusually low noise levels are required, would appear to involve a comparative cost study of external and internal sound level reduction or possibly a combination of both.

As a result of the almost universal use of sound meters for commercial measurements there is a tendency to consider weighted sound levels as identical with loudness levels. Actually as the author has illustrated in his paper there may be considerable deviation for pure tones. The situation becomes more complex for sounds composed of harmonically related components such as exist in transformer noise. Nevertheless weighted sound levels have been found to be reasonably reliable when used to compare the loudness of transformers. This is fortunate since the essential requirement for standardization is that the method of measurement chosen yield a reliable index of loudness and not necessarily the loudness level. A considerable measure of the success of sound level comparison is due probably to the similarity in frequency spectrum and relative component intensity in the noise produced by the majority of transformers. For these transformers, standards could be formulated in terms of either 40 or 70 weighting. A particular standard on the 70 weighting will be higher than that on the 40 weighting, but each will correspond to approximately the same loudness level.

Any change in weighting at higher levels, such as suggested by Mr. Murray, would stem from a desire to bring the numerical value of the standards closer to loudness levels. Refinements of this type involve analytical problems such as the masking effect of harmonically related components as well as application problems, that is, whether the standards should reflect the loudness at the transformer or at points at which the disturbing effect may be felt. These problems are still in the stage where differences of opinion exist. It is well to realize, however, that if we confine our attention to the fundamental requirement, namely that the weighting provide a generally reliable index of loudness, the problem is less difficult. From this point of view, the present 40 weighting is probably the natural choice for its simplicity.

The evaluation of the resultant transformer level at large distances in terms of the standard 1-foot measurements represents an important field problem. Mr. Murray has presented useful empirical data on the rate of variation of level at considerable distances. One of the factors entering into the resultant level which is frequently overlooked is the physical size of the transformer. Although the actual sound fields in the vicinity of a transformer are rather complex, it is possible to draw some general conclusions by considering a spherical source. The average sound intensity I_d produced at a distance d by a large sphere of radius R whose surface is pulsating with a velocity amplitude v at a frequency of wave length λ is given by

$$I_d=\frac{\rho c v^2}{2}\left(\frac{R^2}{d^2}\right)\left[\frac{\left(\frac{2\pi R}{\lambda}\right)^2}{1+\left(\frac{2\pi R}{\lambda}\right)^2}\right] \qquad (1)$$

where ρ is the density and c the velocity of sound in air. In order to express I_d in terms of the average intensity I_t measured one foot from the transformer some assumption must be made about the form of the wave at this distance. If we assume the wave to be spherical our standard pressure responsive sound meters would indicate an intensity

$$I_t=\frac{\rho c v^2}{2}\left(\frac{R^2}{R_1^2}\right)\left[\frac{\left(\frac{2\pi R}{\lambda}\right)^2}{1+\left(\frac{2\pi R}{\lambda}\right)^2}\right] \qquad (2)$$

where R_1 is one foot greater than the radius R. Substituting equation 2 into equation 1

$$I_d=\frac{R_1^2}{d^2}I_t \qquad (3)$$

On the other hand if we assume the wave at one foot is effectively plane

$$I_t=\rho c v^2/2 \qquad (4)$$

and equation 1 can be written

$$I_d=\frac{R^2}{d^2}\left[\frac{\left(\frac{2\pi R}{\lambda}\right)^2}{1+\left(\frac{2\pi R}{\lambda}\right)^2}\right]I_t \qquad (5)$$

For frequencies whose wave lengths in air are small compared with $2\pi R$ both equation 5 and equation 3 indicate a variation of intensity approximately as the square of the radius. For wave lengths that are of the same order of magnitude as $2\pi R$, equation 5 indicates a higher rate of variation which approaches the fourth power of the radius for wave lengths large compared with $2\pi R$. At a frequency of 120 cycles per second the wave length in air is approximately ten feet, so that if equation 5 is valid it may be possible to observe a fourth power variation for smaller power transformers. For larger power transformers the rate of variation will probably be close to the second power of the linear dimensions.

Based on the foregoing reasoning, we would expect the relative size of two transformers to produce, at a remote point, a difference in level given by

$$\text{Decibel difference}=10\log_{10}\left(\frac{L_1}{L_2}\right)^n \qquad (6)$$

where L_1/L_2 is the ratio of the linear dimensions of the two transformers and n may vary from two to four. If, for example, one transformer has twice the linear dimensions of another, then, even though they have identical levels measured at one foot, the smaller transformer may still be from 6 to 12 decibels lower than the larger transformer at say 200 feet.

Because of the simplifying assumptions involved in the analysis, the exact effect of size on resultant level will have to be established by field tests. The analysis presented is intended to call attention to the influence of transformer size. In this connection it is interesting to note that major advances[3] have been made in recent years in size reduction. The introduction of oriented steel,[4] the formfit construction[5] for shell form power transformers and forced oil cooling[6] all have tended to markedly reduce the size of modern transformers and thus decrease the effective level at large distances.

J. A. Adams (Philadelphia Electric Company, Philadelphia, Pa.): The subject paper is of considerable interest to the Philadelphia Electric Company, not only because some of the conclusions parallel our experience but due to the comprehensive and informative treatment of the problem. We feel that the author has produced a useful summary in a readable manner of the major factors involved in transformer noise from an operating point of view. We concur that the present noise level standards are too high and that the present standards for noise level determination should be revised to more accurately stimulate the response of the human ear.

The Philadelphia Electric Company has been becoming increasingly aware of the transformer noise problem, not only in connection with the reaction of nearby residents but also in generating stations, particularly where noise emission of large power banks located near offices of superintending personnel could become a disturbing and annoying factor. In this connection, in order to establish an acceptable noise level for the 100,000-kva 66–13.2-kv forced-oil cooled transformer banks at one of our generating stations, measurements were made in 1945 on existing large power transformer installations on our system. At that time, it was recognized that frequency and relative intensities would affect the human ear in a manner different from the response of a decibel meter. Throughout these tests, the transformer noise frequency differences between installations were clearly noticeable. Based on the combined reaction of the listeners, it was concluded that a design level of approximately 85 decibels without fans and 90 decibels with fans would be acceptable. It is interesting to note that the present NEMA Standard establishes an audible sound level of 83 decibels for a transformer of this type and rating.

The following example of the noise problem in residential areas appears to substantiate the conclusions reached by the author of the paper. The substation involved, located in a quiet residential section, is constructed with two 7,000-kva 13,200–2,545-volt, 3-phase to 2-phase, 60-cycle oil-insulated self-cooled outdoor transformers located in outdoor courts. These courts extend from the west wall of the building proper and are bounded on the rear by the building wall, on the sides by brick walls and originally on the front by Transite covered removable framework with an air space of approximately two feet at the ground level. Wall clearance at back and sides of the transformers is 9$^1/_2$ feet and to the front (removable wall) is 6 feet. The transformers involved have a NEMA test noise level of 64 decibels (40-decibel scale), 5 decibels below allowable.

Almost coincident with the initial energizing of these banks, a noise complaint was received from a resident located approximately 200 feet distant diagonally opposite the west wall of the substation. Of particular interest, from the noise frequency point of view, is the fact that the complainant stated that his dogs were made restless and nervous by the transformer noise.

Check sound level measurements (on 70-decibel scale) made in the transformer courts gave an average of 86.6 decibels. Measurements made external to the substation varied from 58 decibels on east side to 75 decibels along the west wall. Twenty feet out from the west wall, the noise level measured 70 decibels. While it was considered from these measurements that the noise level of the installation was not excessive, the final solution of the problem consisted of completely closing up the west wall of the transformer courts.

J. H. Mahoney (Boston Edison Company, Boston, Mass.): Representing the Boston Edison Company, I would like to present a few of our experiences with transformer noise problems.

1. In the transformer yard adjacent to one of our generating stations, we recently installed a 35,000-kva 110/14-kv transformer. Although noise level is no particular problem at this location, it was found that the doors of the control cabinets vibrated excessively. These doors were made of thin metal which actually chattered due to the transformer vibration. This noise was eliminated by the installation of angle-iron braces across the back of the doors.

2. At one of our recent outdoor substations we installed a 7,500-kva 66/14-kv transformer. In this case the inert-air equipment vibrated so seriously that the gauges were broken. This condition was corrected by constructing a separate foundation for the gas equipment. Our laboratory made audio sound level tests at this location, using a General Radio type *759* sound level meter, and as recommended by the NEMA Standards for Transformers in the section covering Audio Sound Levels for Distribution and Power Transformers.[1] The maximum sound level was 75 decibels; the arithmetical mean was 67.2 decibels (for 34 readings). The NEMA standard for this transformer is 72 decibels. A substantial part of the noise level, on the side of the transformer where the nitrogen apparatus is located, was caused by vibration of that cabinet and the apparatus therein. Readings taken one foot in front of this cabinet, with the cabinet door open, gave 84 and 77 decibels at one-third and two-thirds height of the transformer.

3. In one of our strictly residential areas, we have a new unit substation which has two 5,000-kva 14/4-kv transformers. These transformers are approximately 42 feet apart. Using the same methods and instruments as above, the maximum sound level was found to be 73 decibels; the arithmetical mean for 30 readings was 64.7 decibels for one transformer, and 62.8 for the other. The NEMA standard for these transformers is 68 decibels. Sound level measurements were then taken at two other locations with the microphone on a tripod at a level of about five feet.

With the microphone on the sidewalk across the street from the station, approximately 83 feet from the nearest transformer, the following readings were taken:

	Decibels
No traffic	44
Light traffic	56
Heavy traffic	65
Diesel train (20 feet from rear of station) with light traffic	62
Bus accelerating	71

With the microphone at the rear of the station yard approximately 20 feet from the rear transformer and approximately 20 feet from the railroad tracks:

	Decibels
Normal	52–56
Steam engine passing	88
Remainder of train	83
Diesel engine passing	90
Remainder of train (express)	88

4. At one of our 110-kv Ring Stations we recently installed an 18,000-kva 110/14-kv transformer, and again using the same instruments and methods as above, we found the maximum sound level to be 76 decibels; the arithmetical mean for 60 readings was 71.25 decibels. The NEMA standard for this transformer is 77 decibels.

I have talked with several of our operating personnel and it seems to be a general opinion that although the various sizes of transformers meet the NEMA requirements, these requirements are much too lenient. They would like to see the standard values reduced to at least 60 decibels, and possibly lower.

We are now considering seriously the necessity of including noise-level limits in our specifications for the transformers, particularly for residential areas.

The transformers which I have reported on were not made by any one manufacturer. In fact, there were three different manufacturers' equipment involved. We, therefore, feel justified in saying to all transformer manufacturers that more attention should be given to design characteristics to reduce noise and to the mounting of accessories, the fabrication of boxes and the bracing of radiators.

1. See reference 7 of the paper, pages 33–34.

T. D. Gordy (General Electric Company, Pittsfield, Mass.): Mr. Murray is to be commended for gathering into one paper so much information that has been published previously in many wide and varied papers. In so doing, he has brought into one place the important factors dealing with measurement and evaluation of noise levels and, at the same time, has pointed out the importance of the noise problem to the power system engineer.

One important factor which was stressed is that in evaluating noise, so far as the ear is concerned, component frequencies as well as component intensity levels must be known. These frequencies and intensity levels are necessary if relative loudness is to be evaluated. This same idea of obtaining frequencies as well as intensity levels has been carried over into his recommendation of determining component frequencies along with sound level meter readings of transformer installations.

It is quite true that magnetostriction is one of the driving forces contributing to noise emitted by transformers. However, it is not necessarily the magnitude of the magnetostriction that is so important as it is the shape of the a-c magnetostriction versus flux density curve. It is the shape of this curve that determines the harmonic content of the vibrations caused by magnetostriction. Since the human ear and the sound level meter discriminate between frequencies, it is obvious that the shape of this curve is what determines predominating frequencies in transformer noise, such as 120, 240, 360, and 480 cycles. These are not necessarily the predominant frequencies in all transformers as we have found from our tests. In some cases, the predominant frequency may be as high as 1,200 cycles. Other sources of noise in the transformer are gaps and joints, resonating parts, coils, and vibration from interaction between core and coils. The importance of these sources varies with the design and transformer characteristics.

Mr. Murray has brought out another very important consideration in making noise tests in the field. Such items as temperature, background of the ambient sound level, stray fields, reflecting walls, buildings, or other transformers cannot be overlooked in field testing. Even if the installation is out of town, annoying factors such as airplanes, chirping crickets, barking dogs, and quacking ducks must be tolerated. Evaluation of the transformer noise without considering these bothersome background noises is meaningless.

We check Mr. Murray's change in sound level of 2 to 3 decibels for a 10 per cent change in voltage. This, of course, varies some from design to design, but the figure of two to three is an over-all average which we have found. As Mr. Murray points out, some investigators have found that noise level is independent of load of the transformer. This is true under certain conditions; but depending on the size, type of windings and core, and the winding that is excited, the noise level may be a function of the load. Not only is it a function of the magnitude of the load but also of the load power factor.

The question of which weighting network should be used in evaluating transformer sound levels is one which must be studied thoroughly before present practices are changed. It is true that the 40-decibel weighting network does tend to give low readings when high sound levels are being measured, but it is doubtful if these high sound levels exist at the point where complaints may arise. They do exist one foot out from the transformer contour, but they fall off in accordance with the 4.5-decibel rule obtained by Mr. Murray. Therefore, at some distance from a transformer, the level is no longer so high that the 40-decibel weighting response would be too inaccurate. In order to evaluate transformer noise, a set of standards must be written that will enable all transformers to be tested under very nearly the same conditions. This automatically requires testing at distances from one to a few feet from the transformer contour. Since this level will be diminished when it gets to the observer, it is questionable as to whether or not it is desirable to go to a 70-decibel or flat weighting network for measurements one foot out from the transformer. This whole problem of weighting, microphone location, and distance from the transformer to the microphone should be thoroughly studied by both system engineers and manufacturers in order to arrive at a method of evaluating transformer noise that will be more satisfactory than present standards.

The manufacturer has not overlooked the noise problem in designing large power transformers. He does have other problems, however, that must be considered along with the noise problem. Measures which would reduce noise level cannot always be incorporated in the design because of other characteristics or functions of the design. As a result, at the present state of the art, any decrease in noise level which is built into the transformer will result in a more expensive unit. For example, in one design that was studied, to obtain a reduction in noise level of 10 decibels weight of the transformer was increased 58 per cent which resulted in an increase of 25 per cent in cost. The problem then arises as to whether the extra cost should be put into the transformer itself, or put into buildings or enclosures surrounding a transformer having standard noise levels. There are certain installations which must have exceptionally low noise levels. Manufacturers are well aware that such conditions do arise, but it does not appear advisable to handicap all transformer lines by increasing cost in order to obtain the low noise levels required for these special installations. Systems operating in thickly populated areas are much more aware of the noise problem than those operating in less thickly populated districts, and it is only reasonable that these operators who have unique noise problems may have to pay premiums for obtaining low-noise-level transformer designs.

What noise levels at installations will be acceptable in these metropolitan areas must be determined by the operating companies. Once these satisfactory installation noise levels have been determined, it may properly become a question of economic balance as to whether it is practical to actually design for these levels in the transformer, or whether external means such as various types of enclosures have to be resorted to. At the present time, any method to reduce transformer noise level will be expensive, and this excessive expense must be recognized by operating companies.

F. Von Voigtlander (The Commonwealth and Southern Corporation, Jackson, Mich.): The use of the loudness scale instead of the decibel scale has been explored quite extensively by the signaling apparatus industry with which the writer was formerly connected for some ten years. Experience there indicates that those who work in acoustics prefer decibels for noise level measurement. They reason and calibrate in decibels and the loudness unit requires translation when it is used. In its earlier application to sound signal output rating, the loudness unit was favored because it was thought the customer, usually being nontechnically trained, could evaluate more easily the difference in output between two signals, say one of 88,000 loudness units output level and another of 215,000 loudness units, than if the output level were rated as 100 and 110 decibels respectively. Several years' experience however showed that those who were concerned at all about loudness levels preferred the decibel unit in their work and the loudness unit did not have the popular appeal that was expected of it. The extent to which noise is disturbing depends on so many other factors than the loudness level of the source itself that the introduction of loudness units seems merely to add confusion to the problem.

Whether the 40-decibel, 70-decibel or the flat scale of the sound level meter should be used for transformer noise measurement could become the subject for considerable discussion but it would be of no practical value. There does not appear to be any good reason for not using the flat scale for this particular application. In the frequency ranges of interest the flat scale will give the more accurate results as pointed out by the author. The flat scale is used widely in other applications of the sound level meters for this same reason. The writer agrees with the author that the specifications should be changed to use the flat scale rather than the 40-decibel scale.

Exception must be taken to the author's statement that the 5-decibel tolerance allowed by the ASA standard for sound level meter readings[1] is considerable, and to the statement that two equal sources of noise when sounded together would give a reading 3 decibels higher than when one is sounded alone.

Noise measurements are not exact in the usual sense of electrical measurement accuracy. However, this is of very little practical consequence as the human ear is hardly able to distinguish a level difference as great as 3 decibels. For this reason a variation of 2 to 5 decibels between instruments is not as bad as it may seem. Standardizing instruments to obtain a correction within these limits is frequently of little value as the more popular types of instruments will not hold their calibration that closely under ordinary conditions of use.

Sounding two equal sources of noise together will not give anything near 3 decibels more than the sound level of one sounded alone. In fact with ordinary sound level meters the difference between both and one would not be measurable.

The author states that only the frequency range from 120 to 480 cycles needs to be considered in transformer noises. This is surprising and it is presumed that it is due to the low natural response frequency of the relatively large sections found in power transformers even though the human ear is very much more sensitive to noises in the 1,000-cycle range than to those in the 120-to-480-cycle range.

While low level of transformer noise can be very important in those few cases where transformers are located in quiet residential neighborhoods, it would not seem economically justified to increase the cost of standard transformers for the sake of getting them all down to an ideal noise level. The usual compromise of as good a job as we can get without appreciable increase in cost would seem to be in order here just as it has been in so many other engineering matters. Where very low levels of noise are required the extra cost of such provisions would have to be justified by the particular circumstances. Excessive transformer noise just as excessive noise from any other equipment, may properly lead one to question the adequacy of the design or construction, so that reasonable noise levels may well be taken as an attribute of product quality.

REFERENCE

1. See reference 6 of the paper.

C. S. Murray: Mr. Wray suggests the use of an acoustic tank liner to obtain reduction in the transformer noise. In reference 11 of the paper, Mr. Forrest discusses a liner which may be similar to that which Mr. Wray has in mind. In Mr. Forrest's case, a 20,000-kva transformer was built with a double steel tank, the inner tank being resiliently supported from the other. A reduction of 10 decibels was claimed for this construction. In reference 13 of the paper, Mr. Churcher and Mr. King discuss a similar construction for distribution transformers. The reduction in this case amounted to about 2 to 4 decibels.

Mr. Blomqvist points out that an appreciable reduction in transformer noise will result at points remote from the transformer if the sound power can be made predominantly of a frequency of 120 cycles per second. This is fundamentally sound and the possibilities of doing this should be reviewed by transformer designers. It is interesting to note from Figure 1 of the discussion that transformer *B* emits a noise which at a distance of 500 feet from the transformer has a calculated loudness level value of 57 phons. The intensity levels given for transformer *B* approximate what might be obtained from a 138-kv 60,000-kva transformer designed in accordance with NEMA specified sound levels. There is little doubt that such a transformer would cause a noise complaint at residences located up to distances somewhat beyond 500 feet from such a transformer.

Mr. Fugill's comments on the status of transformer noise around 1930 is very interesting and certainly points out how far we have come since that time. Mr. Fugill's comment that several reference levels were being used is worthy of further comment. Even as late as 1935 there was great confusion as to what reference level should be used. At that time a tentative reference pressure of 0.0002 dyne per square centimeter (same as the reference in use today) was being considered. Many had been using a reference pressure of 0.001 dyne per square centimeter. The adoption of the 0.0002 value resulted in obtaining sound levels 14 decibels above what had been obtained in the past. It took a few years to discuss noise values using the different reference level. Considerable noise data around 1930 to 1935 failed to indicate the reference level and as a result it becomes of little value.

I agree with Mr. Fugill that the answer to lowering the permissible noise levels is not to reduce the limits arbitrarily. It is felt that manufacturers should give this subject considerable study and arrive at means by which transformers can be built at low noise levels economically. I further agree with Mr. Fugill that the whole noise problem be given industry-wide consideration. More and more manufacturers of other electric and mechanical equipment are beginning to believe that something can be done about this noise problem and have begun to take steps in connection with it. It demands the co-operation of all concerned.

Mr. Bennon has pointed out that even though two transformers have identical sound levels when measured at the 1-foot distance, the smaller physical size of transformer may be from 6 to 12 decibels lower than the larger transformer at the 200-foot distance. Power engineers experienced in the noise emitted by distribution and the smaller power transformers should consider this when buying the larger power transformers. This point should also be considered by those responsible for transformer noise standards.

Mr. Bennon states that a considerable measure of the success of sound level comparison is probably due to the similarity in frequency spectrum and relative component intensity in the noise produced by the majority of transformers. A few tests made on six power transformers, of two different manufacturers and ranging from 25,000 to 70,000 kva rating, does not support this statement. A frequency analysis was made at a number of points around each transformer and the values obtained at the different points for each frequency were averaged. It was found that for one transformer the 120- and 240 cycle components predominated; for another transformer the 120- and 360-cycle components predominated; for the remaining four either the 120-, the 240- or the 360-cycle component predominated. Further tests made on four 75,000-kva transformers, at a point about 30 feet distant from each, showed that for two of these transformers of one manufacturer the 120-cycle component predominated. For the other two transformers of a different manufacturer the 360-cycle component predominated. Data obtained by others are similar.

Mr. Bennon brings in the question of simplicity for the noise measurement. The power engineer also is looking for simplicity, but if that simplicity is not going to give him the proper information and allows him to install a transformer that is too loud for a given neighborhood, he is going to abandon the idea and look for something better. It must be borne in mind that once a transformer is purchased for a given sound level and that value of sound level is proved by test, the cost of quieting it, if necessary, becomes the sole problem of the power engineer. The value or values quoted must give the power engineer sufficient information so that he can be fairly sure, without guesswork on his part, how loud his transformer is going to be in the neighborhood where it will be installed.

Mr. Adams' experience with transformer noise levels is interesting. In regard to the noise emitted by the 100,000-kva bank, Mr. Adams states that based on the combined reaction of the listeners, it was concluded that a design level of approximately 85 decibels, without fans, would be acceptable. Mr. Adams does not give the frequency components of the noise nor whether there are any walls or other buildings between the transformer and the offices of superintending personnel. Therefore, it is somewhat difficult to evaluate the noise at the offices. It is assumed that the listeners were company personnel. I question if the same results would have been obtained from noncompany residents, if any, say within an unobstructed distance of less than 1,000 feet. In the case of the 7,000-kva transformer banks, I assume that after the west wall was constructed, no additional cooling for the transformer banks was needed since no mention was made of it. This would agree with the findings of Mr. Fugill.

Mr. Mahoney's experience is valuable information for both the power engineer and the transformer designer. In case 3, where tests were made remote from the transformer, much more valuable information would have resulted if a sound analyzer had been used to measure the components of the transformer noise.

Mr. Gordy brings out that the noise level of a transformer may not be independent of load, but may be a function of the magnitude of the load and the load power factor. The results of a small number of tests on power transformers have indicated that there may be a change in the component frequencies of the noise due to load even though the average sound level remained about the same. Knowing this, it was stated in the paper that additional data on this subject should be obtained.

Mr. Gordy's views on the present use of the 40-decibel weighting response is not surprising. There are bound to be differences of opinion on such a subject as was pointed out by Mr. Fugill in his discussion. Such differences of opinion can best be solved by a co-operative effort of the electrical societies and it is gratifying to know that a working group in the AIEE Transformer Committee will study the transformer noise problem.

Mr. Voigtlander takes exception to my statement that the 5-decibel tolerance allowed for sound level meters is considerable. Distribution transformers have been removed from service due to noise complaints and have been replaced by others from which no further complaints have been received. Average sound level measurements made on the original and also the replacement transformer in the laboratory show that 5 decibels could be the difference between a quiet and a noisy transformer. The American Standards for Sound Level Meters, reference 6 in the paper, recognizes that differences of practical importance may be expected between the results obtained with different meters unless corrections are applied to take into account deviations of the individual meters from the design objective. As a result a method for calibration of the individual meter is given in Appendix "C" of that Standard.

Mr. Voigtlander also takes exception to the statement that two equal sources of noise increase the sound level by 3 decibels over that value when either is sounded alone. Theoretically, if the sources are equal, each source would emit the same amount of sound energy. Therefore, if we double the sound energy, we should, from the definition of a decibel, get an increase of 3 decibels. Appendix "B," of the Standard gives a test for the rms addition. Assuming that Mr. Voigtlander's meter does meet the test for addition, it may be that he is basing his findings on actual transformer tests. It is possible that a point can be selected between transformers where the 3-decibel law would not appear to hold. It is possible to have two similar transformers with equal average sound level values and each of which could have sound level values opposite a point which differed by 10 decibels. The transformer with the lower sound level opposite that point would not materially add to the sound level indicated by the other.

Mr. Voigtlander believes that there are only a few cases where transformers are located in quiet residential neighborhoods. I question this. There are an increasing number of unit substations being installed at load centers with housing fairly close. There is an increase in low-cost housing being located adjacent to generating and substations having large power transformer installations. There was a time when locations such as this were not desirable for housing but today it often happens that it is the only available land in that area. Any power company which is expanding its existing station and installing power transformers out-of-doors, is susceptible to noise complaints. The company may not have a problem today but, unless it owns considerable land about the station or the land is not suitable for housing, it may have a problem in the near future. There are known cases of power companies now having their first transformer noise complaints. The residence does not necessarily have to be adjacent to the station. I mentioned in the paper a case where the complainant was located over a quarter of a mile from the transformer installation. No company can afford even one noise complaint because it has been my experience that as soon as one complaint is registered the public begins to listen for other noises and a series of complaints arise due to operation of other equipment.

Controlled Temperature and Insulation Protection in the Operation Of Power Transformers

W. W. SATTERLEE
MEMBER AIEE

R. D. REED
ASSOCIATE AIEE

MOISTURE and oxygen in varying amounts are the ever-present enemies to the satisfactory and continued operation of liquid immersed transformers. The life of the oil and insulation in a transformer cannot be determined accurately by laboratory tests since it is difficult, if not impossible, to make such tests so as to duplicate operating conditions.

When transformers are operated with the oil in them exposed to the atmosphere, objectionable products are formed from the combination of the oxygen present with the oil. These harmful products are largely water, organic acids which may be water soluble or water insoluble, neutral products and solid precipitates commonly known as sludge. Thus heat, oxygen, and the products of oxidation of oil account for the slow decomposition of cellulose materials. The result is a mechanical weakening of the solid insulation in a transformer and an addition of impurities to those already in the oil.

This deterioration of transformer oil and cellulose insulating materials can be reduced appreciably, if not almost eliminated, depending upon the methods used to prevent the entrance of moisture and oxygen into transformers.

Oxygen is probably responsible for the greatest amount of deterioration; although, as far as oil and insulating structures in transformers are concerned, water is undoubtedly the most objectionable impurity whether it be present as moisture from the inbreathing of air or formed as a by-product of oxidation. Water, directly or indirectly, is the cause of more electrical breakdowns or other types of unsatisfactory operation of transformers than any other impurity.

Protection of the oil and cellulose insulation used in transformers is afforded in varying degrees by what are termed free-breathing, restricted or controlled breathing and completely sealed-tank construction. Thus, in order to determine under actual operating conditions the effects of different forms of protection to oil immersed transformers, a group of small transformers has been under life test operation for more than five years.

Fourteen transformers, representative of power transformer design, were started on life test in May 1943. The operation of these transformers is being continued indefinitely. Physically, all of these transformers are of the same design, each using a round tank, cover-mounted bushings, and containing the same amount of oil, see Figure 1. Their low-voltage windings are of the cylindrical or barrel type construction, while the high-voltage windings are of the continuous-wound pancake-section design. In order that samples of the conductor insulation used in the windings of these transformers can be had for test purposes, a small coil of the same design as the high-voltage windings is mounted in the top oil of each transformer and connected in series with its high-voltage winding.

All 14 transformers are installed and operated under outdoor service conditions. The identification of each transformer under test, including a set of pilot-windings sealed in a tank of oil and operating only at ambient temperatures, is as follows:

Transformer Number 1—Sealed-tank, equipped with activated clay filter.

Transformer Number 2—Sealed-tank, equipped with aluminum oxide filter.

Transformer Number 3—Sealed-tank.

Transformer Number 4—Open air breathing, equipped with aluminum oxide filter.

Transformer Number 5—Open air breathing. Low- and high-voltage windings were treated with varnish.

Transformer Number 6—Open air breathing.

Transformer Number 7—Sealed-tank, equipped with breathing regulator.

Transformer Number 8—Expansion tank, 2-compartment type.

Transformer Number 9—Expansion tank, conventional type.

Transformer Number 10—Inertaire. Low- and high-voltage windings were treated with varnish.

Transformer Number 11—Inertaire.

Transformer Number 12—Inertaire, equipped with aluminum oxide filter.

Transformer Number 13—Inertaire—125 degrees centigrade hottest-spot.

Transformer Number 14—Inertaire—105 degrees centigrade hottest-spot.

Tank Number 15—Pilot windings, sealed in a tank of oil.

All transformers are subjected to identical loading and operating conditions, except that transformers number 13 and number 14 are arranged to operate at hottest-spot winding temperatures of approximately 125 and 105 degrees centigrade, respectively, and the tank of pilot coils number 15 operates at ambient temperatures. Transformers number 1 to number 12, inclusive, operate at a hottest-spot winding temperature of about 115 degrees centigrade.

Paper 49-193, recommended by the AIEE Transformer Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer General Meeting, Swampscott, Mass., June 20–24, 1949. Manuscript submitted November 15, 1948; made available for printing May 2, 1949.

W. W. SATTERLEE is Division Engineer and R. D. REED is Design Engineer, both with the Westinghouse Electric Corporation, Sharon, Pa.

The authors express their appreciation to their associates in the Westinghouse Electric Corporation, E. W. Tipton and J. G. Ford, who contributed to the preparation of this paper.

Description of Installation

The 14 transformers and the tank of pilot coils were installed outdoors and arranged according to the plan view shown in Figure 2. The transformers were platform-mounted which raised them about two feet above the ground level, making their lower drain valves easily accessible for the removal of samples of oil. Figure 3 shows the complete installation.

The transformers were connected for loading by the familiar load-back method which is commonly used in making temperature tests. All of the transformers were magnetized by connecting their high-voltage windings in parallel, thus insuring that all units always operate with essentially the same no-load losses. The secondaries of all transformers are supplied with a load current from an adjustable source of sufficient capacity to get a hot oil temperature of about 95 degrees centigrade with an ambient temperature of 25 degrees. The higher temperature of transformer number 13 was obtained by blanketing its tank and a series reactor was used to get the lower temperature of transformer number 14.

On May 17, 1943, the transformers were started on life test with the following load cycle:

Load on 8:00 a.m. Monday, load off 3:00 p.m. Tuesday.

Load on 8:00 a.m. Wednesday, load off 3:00 p.m. Thursday.

Load on 8:00 a.m. Friday, load off 3:00 p.m. Saturday.

Each transformer is equipped with a thermometer to indicate its hottest oil temperature. Oil temperature and ambient temperature readings were taken and recorded at the beginning of each loading period and after the completion of each 31 hours of operation. This record of oil and ambient temperatures serves to show the extent to which each transformer was loaded during operating periods.

In order to accommodate the servicing of these transformers to factory working hours, the loading cycle was changed; first, after $6^1/_2$ months' operation, to two 55-hour periods per week and then, changed slightly again, $2^1/_2$ years later to have load on at 8:00 a.m. Monday, load off at 3:00 p.m. Tuesday; load on at 8:00 a.m. Thursday, load off at 3:00 p.m. Friday; load on at 8:00 a.m. Monday and so on. This loading is being continued.

Record of the Data Obtained

The object of this life test is to observe and to determine the changes in the condition of the oil and the insulating materials in these transformers over a long period of time and, insofar as possible, under actual operating conditions.

Table I. Oil and Insulation Power Factor

Transformer Number	Description of Transformer	Power Factor High to Low and Iron*	Oil Power Factor
1	Sealed clay filter	0.35	0.03
2	Sealed aluminum oxide filter	2.78	4.17**
3	Sealed	1.48	0.28
4	Open air aluminum oxide filter	2.34	2.83
5	Open air varnished coils	0.88	0.38
6	Open air	2.13	2.29
7	Breathing regulator	0.58	0.28
8	Two compartment expansion tank	1.17	0.29
9	Conventional expansion tank	0.87	0.79
10	Inertaire varnished coils	0.43	0.235
11	Inertaire	0.60	0.375
12	Inertaire aluminum oxide filter	0.26	0.045
13	Inertaire—125 degrees centigrade hottest spot	3.26	0.295
14	Inertaire—105 degrees centigrade hottest spot	2.00	0.265
15	Pilot coils		0.20

* Insulation power factor data taken at a temperature of approximately 25 degrees centigrade for all transformers. Transformer had been on test 1,446 days (3.96 years).

** Open valve—see text.

Table II. Color of Oil

	Days on Test	44	80	187	348	701	819	1,446
	Years on Test	0.12	0.22	0.51	0.95	1.92	2.24	3.96
Transformer Number	Description of Transformer							
1	Sealed clay filter	1	1	1	1	1	1	1.5

The initial condition of the oil was checked just before the start of the life test. Samples of oil taken from each transformer were tested for color, neutralization number, water soluble acids, dielectric strength, and interfacial tension.

A complete temperature record has been kept on the operation of each transformer during the entire life test to date. Oil and ambient temperatures were recorded at the beginning and at the end of each loading period. Since hottest-spot winding temperatures could not be recorded, they had to be determined and with relation to hottest-oil temperatures from data which were obtained from temperature tests made on two of the transformers prior to the start of the life test. For example, test data obtained on transformer number 6 are:

No load loss, watts	219
Copper loss, watts	570
Total loss, watts	789
Top oil temperature rise, degrees centigrade	64
High voltage winding average temperature rise, degrees centigrade	70.5
Gradient, degrees centigrade	6.5
Load in kilovolt-amperes	13.

When the transformers were started on life test, it was found that operating conditions made it necessary to excite them at a voltage slightly lower than that at which the original temperature tests were made. Correcting the losses to the lower voltage changed the data as follows:

No load loss, watts	182
Copper loss, watts	570
Total loss, *P*, watts	752
Top oil temperature rise, degrees centigrade	61.6
High voltage winding average temperature rise, degrees centigrade	68.1
Gradient, degrees centigrade	6.5
Load, *P*, in kilovolt-amperes	12

15	Pilot coils	35.2	29.0				29.6	36.5

Days on Test heads the columns 44 to 1,446.

A winding hottest-spot gradient of 16.5 degrees centigrade was determined by adding 10 degrees, the conventional allowance used for liquid immersed transformers, to the average winding gradient of 6.5 degrees. Then, after making the following assumptions, it was possible to calculate the hottest-spot winding temperatures and hottest-oil temperatures for any loading desired.

1. Ambient 25 degrees centigrade.
2. Oil temperature rise varies as $L^{0.8}$.
3. Hottest-spot gradient varies as $P^{1.6}$.

On this basis the following equations apply to transformer number 6, and thus to all of the other transformers subjected to the life test:

$$\text{Hottest-oil temperatures} = 25 \text{ degrees} + 61.6\frac{L^{0.8}}{752}$$

$$\text{Hottest-spot temperature} = 25 \text{ degrees} + 61.6\frac{L^{0.8}}{752} + 16.5\frac{P^{1.6}}{12}$$

L = total loss in watts
P = load in kilovolt amperes

Curves are plotted as shown by Figure 4 from which the hottest-oil temperatures, corresponding to the hottest-spot winding temperatures, may be obtained for all of the transformers. For example:

Hottest-Spot Winding Temperature, Degrees Centigrade	Hottest-Oil Temperature, Degrees Centigrade	Ambient Temperature, Degrees Centigrade	Oil Temperature Rise, Degrees Centigrade
105	88	25	63
115	95	25	70
125	103	25	78

The desired hottest-spot winding temperatures were obtained by loading and by blanketing the transformers to give the required hottest-oil temperatures. It is recognized that there may be some difference between the relation of the hottest oil and the hottest winding temperatures of the transformers which are blanketed and of those which are not blanketed.

Obviously, a continued change in ambient temperature resulted in a change of the oil and winding temperatures. A temperature record, typical of that kept on all of the transformers since the start of the life test, is shown in Figure 5 for transformer number 6. It may be noted that the oil temperature reaches the required value at an ambient temperature close to 25 degrees centigrade and that the oil temperatures rise and fall with changes in ambient temperatures.

Power Factor

The power factor of the transformers was measured by applying the bridge

Figure 1 (left). Life test transformers

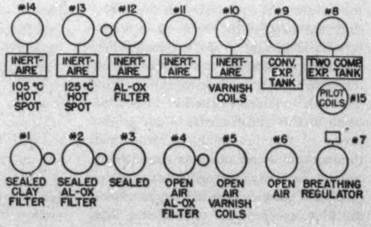

Figure 2 (right). Identification of life test transformers

Figure 3. Life test transformers. View of complete installation

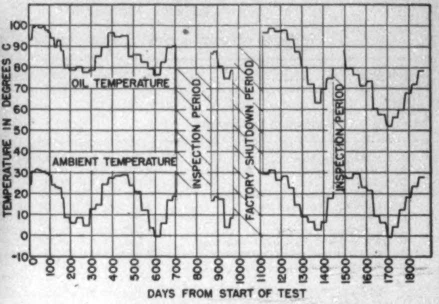

Figure 5. Temperature-time curve for transformer number three

connections from the bushing terminals to ground. The results are shown in Table I for measurements made four years after the start of the life test. In order that the power factor would not be affected by leakage paths over the surface of the bushings, they were cleaned before the measurements were made. The results are rather variable, but it is noticeable that, in general, the transformers with controlled breathing have the lowest power factor. The power factor of the oil in each transformer also was measured after four years of operation and the results are given in Table I. The values of power factor obtained for transformer number 2 and for the oil in it must be discounted, because a valve connecting to the gas space above the oil in the transformer was found open, causing free breathing operation of this unit over a considerable period of time.

Color of Oil

Samples of oil were taken from each transformer at different intervals of time throughout the life test. The changes in color of the oil as the test progressed are shown in Table II. The tabulation clearly indicates the beneficial effects to the sealed units equipped with the filters, since the color of the oil in these transformers is nearest to the original value. The abrupt change in the color of the oil in transformer number 2, as indicated by the value obtained at the last inspection of all of the transformers, is due to the period of free breathing operation and thus a rapid deterioration of the filtering agent. Similarly, the oil in transformer number 7 shows a decided improvement in color as the test proceeded. The reason for this is that a defect was found in the operation of the breathing regulator and the original oil in this transformer was replaced with new oil following 819 days operation.

Acidity of Oil

The total acids measured by the milligrams of potassium hydroxide per gram of oil to neutralize are given in Table III. The acidity should be kept low since oil with too high an acid content is more likely to sludge and to cause rapid corrosion of steel parts. It is evident that the oil in transformer number 1, which is sealed and equipped with a clay filter, has remained low in acid content throughout the life test. Transformer number 2, which was sealed and equipped with an aluminum oxide filter, also contained oil which remained low in acids until free breathing occurred as a result of the open valve. It may also be noted that transformer number 12 contains oil which has low acidity. It is obvious from the results of the test that open or free breathing contributes to the production of acids.

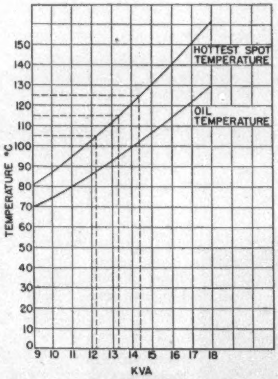

Figure 4. Relation of hottest-spot temperature to oil temperature

Dielectric Strength of Oil

The dielectric strength was measured on samples of oil removed from the top and the bottom of each transformer at seven different intervals during the life test. Five test shots were made on each sample of oil, or a total of ten tests per transformer. Table IV gives the average results of the ten tests made on the oil from each transformer. Although a few values of relatively low dielectric strength were obtained on samples of oil taken from transformers 3, 5, and 6, all other values were high, including those after four years of operation, as indicated in Table IV.

Interfacial Tension of Oil

Tests to determine the interfacial tension of the oil in each transformer were made after four years of operation. Interfacial tension is determined by carefully pouring the sample of oil under test into a beaker of water and measuring, after the oil and water have separated into two layers, the force in dynes per centimeter of length required to pull a planar ring of platinum wire from the water through the interfaces of the water and the oil. The device used to measure interfacial tension is known as a surface tensiometer. The measurement is made under rigidly standardized equilibrium conditions which have been shown in

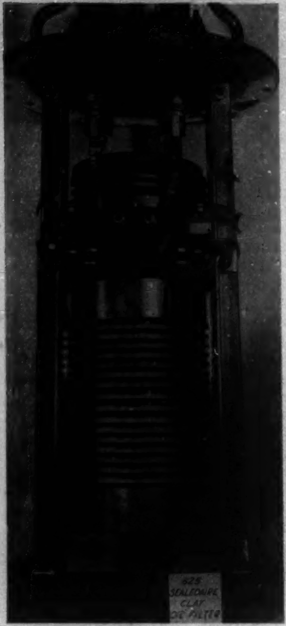

Figure 6. Interior view—life test transformer equipped with clay oil filter

practice to give a reliable indication of the presence of hydrophilic compounds. The interfacial tension data of the oils in these transformers are given in Table V. A high value of interfacial tension is indicative of a satisfactory condition of an oil. A value of 18 is considered by some operators as satisfactory. It may be observed that the transformers, which remained sealed or were operated with controlled breathing, contain an oil having the highest values of interfacial tension.

Mechanical Strength of Paper Insulation

Pieces of the paper insulation were removed from the conductors of the sample coils in each transformer and tested for mechanical strength. In order to make the paper samples suitable for testing, the oil was extracted from them and they were softened with water to facilitate straightening-out the paper samples without breaking them. The paper samples were then dried and tested for tensile strength using a one-quarter inch separation of the jaws of the testing machine. The results of the tests are given in Table VI.

There are many designers and operators who wonder just what correlation there is between the tensile strength of insulating materials and transformer life. In order to obtain some data on this matter, short circuit tests were made on transformer number 5, an open breathing unit, since, as indicated in Table VI, the greatest decrease in tensile strength of the conductor insulation had occurred in this unit. This transformer withstood 5-second short circuits of $2^{1}/_{2}$, 5, and 10 times full load current under sustained voltage without showing any signs of mechanical or electrical failure. Following the short-circuit tests, the transformer was satisfactorily subjected to the disruptive and induced AIEE overpotential tests. Short-circuit tests of the same magnitude will be repeated on this transformer at the next inspection period.

Period Inspections of Transformers

At intervals of approximately two years, the transformers were taken out of service and given a thorough inspection, and a series of tests were made on each transformer to determine its condition.

Insulation power factor and capacity measurements were made immediately after the transformers were shut down so as to obtain values while the transformers were still hot. After the transformers had cooled to the ambient air temperature, the insulation power factor and capacity measurements were repeated. The transformers were then moved indoors where a series of tests were made on each unit, and all units were opened and thoroughly inspected.

The first test made was a disruptive 60-cycle test at the original value of 10,000 volts from high to low and ground, and at 10,000 volts from low to ground. This was followed by an induced voltage test of two times normal voltage for 60 seconds.

Next, each sealed transformer was pressure tested with nitrogen at seven pounds per square inch for one hour to check for leaks which might have developed during the 2-year period of operation. It is interesting to note that no leaks were found.

Following completion of the pressure tests, each transformer was opened for inspection. A view of the core and coil assembly of one of the transformers, as supported from the cover of the tank, is shown in Figure 6. The pancake coil construction of the high-voltage winding is clearly shown in the illustration. While the low-voltage coil is not visible it is of the well-known cylindrical or barrel type design.

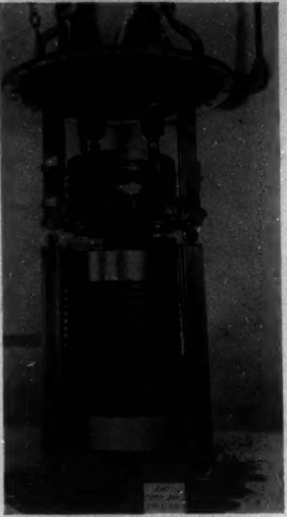

Figure 7. Interior view—life test transformer equipped with open air breather

Resting on top of the core and coil assembly is the sample coil which consists of two sections of the high-voltage winding. The sample coil is connected in series with the high-voltage winding and is thus subjected to essentially the same operation conditions. The purpose of the sample coil is to provide a convenient means of obtaining pieces of the conductor insulation for test purposes by removing one or two turns from the coil at each inspection period.

Photographs of the core and coil assembly of each transformer were made at each 2-year inspection period in order to provide a visual record of the internal condition of each unit. The excellent condition of the sealed-tank unit equipped with the clay filter, transformer number 1, is clearly visible in Figure 6. On the other hand, the effects of moisture and oxygen are very evident in the open-breathing unit, transformer number 6, as shown in Figure 7.

As a part of each 2-year inspection, samples of oil taken from each transformer and a sample of new oil were sealed in glass test tubes. These samples of oil

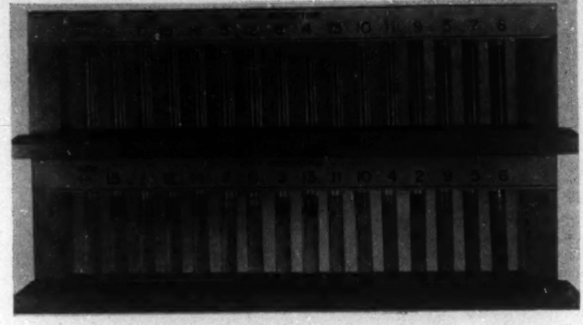

Figure 8. Oil samples taken from life test transformers

were arranged in the order of their color and photographs were made of them, Figure 8. After each inspection of all of the transformers was completed, they were retanked using new gaskets. The transformers were then returned to their outdoor location, and the sealed-tank units with their auxiliary equipment connected were pressure tested for leaks at seven pounds per square inch for six hours. Following this, they were again subjected to the life test load cycle. At present, it is the plan to make the next inspection of the condition of these transformers during the summer of 1949, or after about six years of operation.

Conclusions

Many tests on the aging of oils and insulation have been conducted under carefully controlled laboratory conditions. This type of test is usually accelerated and, although it does show a degree of deterioration of the materials under test, the results are of much less practical value since they are not indicative of actual operating conditions. For instance, W. G. Horsch[1] points out that accelerated laboratory oxidation tests show no correlation with the performance of oils in transformers under controlled test conditions. Therefore, life tests on model transformers, such as described in this paper, are believed to be representative of service conditions and to take into account all of the factors which cause deterioration of oil and insulating materials, and consequently, lead to a reduction in the operating life of transformers.

Table V. Interfacial Tension of Oil

Dynes Per Centimeter

Transformer Number	Description of Transformer	
	Days on Test	1,446
	Years on Test	3.96
1	Sealed clay filter	44.6
2	Sealed aluminum oxide filter	13.8
3	Sealed	20.8

11	Inertaire	20.7
12	Inertaire aluminum oxide filter	39.2
13	Inertaire—125 degrees centigrade hottest spot	21.7
14	Inertaire—105 degrees centigrade hottest spot	23.7
15	Pilot coils	25.9

As with most practical test setups, especially of the magnitude of the one covered in this paper, unforeseen difficulties usually arise as the tests proceed. Thus, it is difficult and sometimes impossible to draw satisfactory conclusions from some of the data obtained. For example, in those tests, the value of the data on power factor is questionable since the transformers operate at very low voltage and, perhaps, the number of measurements made to data are too few.

A review of the characteristics of oil and insulation usually considered in evaluating the condition of oil immersed transformers clearly indicates that the units which are operating under controlled conditions are in the best condition, and thus one may expect a much longer life from these transformers as compared to the probable life of the units which are exposed to restricted or to the free breathing of moisture and oxygen.

For instance, the data on the color of the oil, the acidity of the oil, its interfacial tension, even the power factor of the transformers and of the oil in them, indicate the sealed-tank units, especially those equipped with clay or aluminum oxide filters, to be in the best condition. As with all transformers in service, a relatively high value of dielectric strength of the oil cannot be taken alone as conclusive evidence of good oil and insulation. While the results of the tests for the tensile strength of the conductor insulation show that, generally, the material in the sealed-units is in the best condition, particularly is this true of the filter equipped sealed transformers, the data also indicate the uncertainty of evaluating the operating life of a transformer by the mechanical strength of the conductor insulation. This conclusion is borne out by the fact that transformers which have given uninterrupted service for many years have been found to contain conductor insulation of very low tensile strength, yet the dielectric strength between conductors in the windings of such transformers would be high.

Data from tests of the kind described in this paper, when continued over long periods of time, are of more use than other types of tests in evaluating the condition of transformer oil and insulation or in comparing different methods of oil and insulation preservation now in common use.

Discussion

F. J. Vogel (Illinois Institute of Technology, Chicago, Ill.): I remember when this series of tests was started, and I have been quite curious as to the results obtained. The result expected, when the tests were started, was a real evaluation of the worth of various methods of oil protection, so that controversial opinions might be settled by test data. Naturally, I believe that this is a real service to the industry. I note that the hottest spot was determined by calculation from an assumption of the conventional hot-spot allowance. It seems to me that actual values could either have been measured, or calculated from the actual watts per square inch (or gradient) and the hot oil temperature.

Discussing the results, it would have been desirable had power factor measurements been taken at the start of the tests. However, power factors of less than 0.5 of a per cent for the insulation and of 0.03 or 0.04 per cent for the oil are as low as could be expected for new and well-dried transformers. This would indicate that the sealed transformers with filters had not measurably deteriorated, so far as these properties are concerned. As concluded by the authors, the tests do not indicate much deterioration for the units protected from oxygen, either by sealing or use of inert gas.

The test tube tests made a short time ago entirely sealed in the deterioration products and I believe they showed much more deterioration than the tensile tests reported here. In these tests other materials besides manila paper are present and also in some cases filters were used. The deterioration products then were either diluted or removed. I hope that the presence of these deleterious products might be an explanation of some of the previous vagaries in the experimental data. However, transformer insulation is generally under compression, and hence tensile tests do not prove anything directly as to life. They were chosen rather as giving more reliable test measurements rather than as a direct criterion. I would have liked to have seen results of short circuit tests on transformer Number 13, giving a comparison between varnished and unvarnished coils, with some idea as to the maximum compressive forces in the structure. Still another thing in this respect would be data as to whether there was any shrinkage in the column heights, or loosening of the pressure on the coil clamps. Elaborate means with springs to maintain coil pressure have been used in past practice, although their use now is generally obsolete.

V. M. Montsinger (Pittsfield, Mass.): The authors are to be congratulated for carrying out such a comprehensive set of tests on the protection of oil in transformers. It requires a lot of work to construct and carry out a series of tests as described in the paper. I wish to discuss four of their conclusions.

I agree with some but not all of their conclusions.

Let's consider two statements made in the first paragraph of the authors' conclusion. I agree that tests made on oil at normal temperatures or near normal temperatures are preferable to accelerated laboratory tests. I feel however that there is some question as to whether the use of such extreme cooling and heating cycles represent operating conditions and therefore may lead to erroneous conclusions as to the acceptability of equally good methods of oil preservation. For the conservator and open-type units this method of operation is extremely severe, drawing in more fresh oxygen than would ever happen in power transformers that have core loss and some load loss on all the time. For these units the tests are in effect accelerated tests while for the inertaire and sealed units there is no similar acceleration.

In the second paragraph of their conclusion, I do not understand why the data on power factor is questionable because of the low voltage used. I would ask the authors to explain this.

In paragraph three, I think that all of us will agree that transformers under controlled conditions will have a longer life than transformers exposed to restricted or free breathing of oxygen. In the fourth paragraph the statement that the color, acidity, interfacial tension, and even power factor of the sealed tank units to be in the best condition, in general is true but there are some contradictions in the tables. For example tank number 14, inertaire, has a high power factor. Tank number 11, inertaire, has a fairly low interfacial tension value and tank number 10, inertaire varnished coils, has a high acid content.

My principal objection is to the fifth paragraph namely that because transformers which have very low mechanical strength do not always fail indicates that tensile strength is a poor criterion for evaluating the life of a transformer.

I agree that transformers often operate for extended periods after the mechanical strength is gone provided they are not subjected to severe surges either mechanical or electrical.

I strongly feel that the true life of a transformer is reflected by the mechanical condition of its insulation, especially of its turn insulation. If it cannot resist a surge its true life has been used up. It's really living on borrowed time, and should be removed from service. The trouble is we do not know when it reaches this stage.

P. L. Bellaschi (Sharon, Pa.): This discussion has reference to the economics of power transformers, especially from the application end.

Having been closely connected with and, in fact, instrumental in a good measure to the development reported in this paper, certain comments on the significance of these tests should be in order. In the first place, as I have maintained in previous discussions on the aging and preservation of insulation, tests on miniature transformers are useful in filling in the gap which long since has existed between the results of research tests on insulation as such and the inherently slow-process development resulting from experience on actual equipment in service.

One may justifiably question the significance of some of the results in the tabulations and in the figures and, in fact, their correctness. This is the case in regard to: the mechanical strength tests on the paper insulation, due to probable damage upon its removal from the conductor; the power factor measurements; as well as some of the other data. Therefore, a word of caution in drawing final conclusions is in order, but this should not detract in any manner from the general value of the investigation and from the positive results hereto attained.

Another point one may question is in connection with the true significance of the hottest-spot copper temperatures designated as 105, 115, and 125 degrees centigrade in the tests. These should be considered as nominal reference values and hardly to be taken as equivalent sustained temperatures in the sense we associate continuous temperatures in the standards.

A conclusion of practical significance that can be drawn from these tests is in connection with the relative effectiveness of the various methods of preservation and protection of the insulation. Providing that deterioration of the oil and insulation can be forestalled, as through the use of inert gas (preclusion of air and moisture) and deleterious products eliminated or removed through the use of activated clay, the life of the insulation can accordingly be prolonged materially. In fact, a more effective use of the insulation through higher operating temperatures than was otherwise possible in the past seems possible by a proper utilization of these means. It is an established fact, however, that for prolonged or continuous duty, even with the foregoing protective measures at our disposal, cellulose insulation still has a top hot-spot temperature of about 110 or 115 degrees centigrade that must be recognized. That is, permanent chemical decomposition and damage to the insulation will result if a sustained temperature of about 115 degrees centigrade is maintained.

These tests, as well as other investigations of a similar character and field experience in general, all bear out and further substantiate the inherent conservatism embodied in present standards. Here then we find ourselves face to face with still another opportunity to better utilize present station equipment, to greater economic advantage. A parallel process of rationalization as now is being effected through the application of reduced insulation (see discussion)[1] can be effected through a fuller utilization of the thermal capabilities of oil-immersed transformers and through suitable means of insulation preservation that inherently enhance the life expectancy of the insulation and permit possibly higher operating temperatures.

REFERENCE

1. EXTREMES IN THE INSULATION CO-ORDINATION OF OIL-INSULATED TRANSFORMERS, F. J. Vogel. *AIEE Transactions*, volume 68, part II, 1949 (*Proceedings* T9195). Discussion by P. L. Bellaschi.

W. W. Satterlee: In reply to Mr. Vogel's discussion, we wish to state that before the life test of these transformers was started, the hottest-spot temperatures of two of the transformers were obtained by use of thermocouples in their windings and during load—back run made at different kilovolt-ampere ratings. In other words, we attempted to check actual hottest-spot temperatures against calculated temperatures. In general, the calculated hottest-spot temperatures exceeded the measured temperatures by a few degrees.

We agree that more tests on the transformers for power factor would have been desirable. Also, power factor tests of the oil in the transformers were not made until the 1947, or second 2-year inspection period. It is probable that short-circuit tests will be made on unit number 13 at the next inspection period.

We did find evidence of slight column shrinkage during the recent 1949 inspection of these transformers.

We are quite in agreement with Mr. Montsinger as to the amount of work involved in carrying out this life test program and series of tests on the transformers.

It seems questionable that the operating cycles under which the life test on these transformers is being conducted are especially severe, even if one considers the test as being unfair to restricted and to open breathing units.

The results do show that the transformers with sealed construction or those in which breathing is controlled are afforded the best protection. If a system of protecting the oil and insulation is good under severe operating conditions, then certainly it should be good under conditions less severe, or those which might be called more normal conditions.

The idea in connection with the statement in the paper of questionable data on power factor was intended to mean that had more data on the power factor of the transformers been obtained, and had the transformers under life test been of a relatively high voltage class, then the results on power factor might have been of more interest and perhaps more representative of power transformer operation. It was not intended to convey the idea that the low-voltage transformers used made the results questionable.

We believe one should expect some contradictory results in a series of tests of the kind the paper describes. In fact, this condition or possibility is pointed out in the conclusions.

Whether or not short circuit tests prove the mechanical stability of the insulation in a transformer, or whether the mechanical strength of the turn insulation is any criterion in the length of the operating life of a transformer, it is our belief that continued operation of the life test transformers and periodic inspection and detail tests on all of them will provide much data by which the operating characteristics and life of a transformer may be more fully evaluated.

Our answer to Mr. Bellaschi is that it is difficult to remove insulation from copper conductors without the possibility of some mechanical damage to it. However, extreme care was exercised in obtaining the samples of insulation for test purposes and in making the tests. Comments have been made regarding the power factor tests for one of the previous discussions.

It is not understood exactly what Mr. Bellaschi means by "the true significance of the hottest-spot copper temperatures." The transformers are operated in such a manner that during the loading cycles their windings reach, at least closely, the temperatures given in the paper. However, the transformers do not operate at the specified temperatures continuously. In fact, few power transformers do in actual service.

It is expected that the continued operation of these transformers will provide additional valuable data which will be of much practical use in determining the effects of various methods of protecting oil and insulation in the operation of power transformers.

A Small High-Voltage Bushing Design for High Altitudes

F. J. VOGEL
MEMBER AIEE

H. A. HART
ASSOCIATE AIEE

TRANSFORMERS as component parts for radio service and for fairly high voltages of the order of 10,000 volts occasionally have been required. When in turn they were required to operate at the equivalent of 3.4 inches of mercury pressure and to be corona free, a design problem was presented immediately. There have been several papers written about the problem, with no concrete design procedure given. In this paper, a design procedure for the shape of the porcelain and parts is given, with some test results verifying the design.

A particular transformer design was required to supply 8.6 kv with the midpoint grounded. The porcelains for such a design would have to stand 9.6 kv rms for one minute at atmospheric pressure. Also, they were to be free from corona or radio disturbance at voltages at least up to 25 per cent over rated voltage, or 5.4 kv to ground at a pressure of 3.4 inches of mercury.

In the solution of this problem, the law of similitude was applied directly. This law states that in cases where the parts are in the same proportion and the dielectric field has the same shape, the breakdown voltage will remain constant provided the sizes of the parts vary inversely as the gas pressure. Paschen's law is merely a special case, inasmuch as it refers to uniform fields. This law applies directly to corona rather than breakdown, so that it means that if corona is to be avoided, fundamental data on corona formation is necessary.

Several designs of porcelain were considered, and the bushing, as dimensioned in Figure 1, was the final design. The apparent advantages in the design are:

1. There is no concentration of stress at the edge of the metal parts of the flange or container in air, as in the design shown in Figure 2.
2. There is no concentration of stress in the air at the terminal parts, as in the design shown in Figure 2. The diameter of the terminal rod is the chief factor in the strength, rather than a square edge or point as in Figure 2.

The interior of the assembly required oil filling; therefore, the porcelain was mounted on the bottom of the case, so that the transformer oil filled the porcelain shells. If this were not done the bushing design would have been complicated further.

The advantages cited lead to the big advantage that the design might be corona free up to nearly the breakdown voltage, and hence could be of small dimensions relative to its voltage strength.

To check this, the porcelain according to dimensions shown in Figure 3 was tested. Corona occurred at the edge of the washer on the terminal next to the porcelain at 12 kv. Flashover occurred at 22 kv. These tests were made in air at room temperature and pressure. The assembly then was modified to be similar to the selected design, by adding a fibre washer 1/4-inch long and a metal pipe terminal approximately 0.72 inch in diameter, as shown in Figure 4. Corona then formed on the pipe just above the fibre at 25 kv. Flashover occurred from the pipe to the plate at 26 to 28 kv. Corona also formed on the washer at the extreme end of the pipe at about 18 kv.

In order to determine the voltage at which corona would occur at the flange, the fibre washer length was increased to 7/16 inch and the bushing tested again. Corona occurred at the flange at 29 kv, and flashover at 32 kv. The amount of corona at the flange grew with increased voltage.

The next step was to replace the pipe terminal with one more likely to be the final design. It was made 1/2 inch in diameter, 7/8-inch long, and hemispherical at the end, with provision for a wire to be clamped inside the terminal as shown in Figure 1. Upon test at reduced pressure, 3.15 inches of mercury, corona at the hemispherical end occurred at 5.1 kv, and just above the fibre at 7.9 kv. With number *10* wire extending from the terminal, corona was eliminated except at the end of the wire. The corona voltage at the terminal above the fibre was 7.7 kv. Corona and flashover occurred at about the same time for both the 7.9 kv and 7.7 kv values as given. The string distance from the flange to the terminal was about two inches.

The modified bushing previously described also was tested at room temperature and pressure. Corona at the hemispherical end occurred at 24.5 kv, and at the flange next to the bushing at 32.5 kv. When the number *10* wire was added, corona was eliminated at the cap except at the wire termination, but was observed at the flange at 29 kv.

It is difficult to analyze these data exactly. In the case of the tests at full pressure, it is interesting to estimate the strength of the tube terminal to the plate. For the first tests, the tube was 0.72 inch in diameter, and the string distance from it to the plate was two inches. It might be estimated that the strength of this assembly would be about the same as for a 0.72-inch cylinder inside a 4 + 0.72 or 4.72-inch cylinder. A graph showing the relationship between the corona voltage and separation for concentric cylinders is shown in Figure 5. To estimate the strength, the ratio of outside to inside diameter must be found to locate on a line of constant ratio. This ratio is 6.6 for the preceding case. The voltage corresponding to this ratio and a separation of two

---

Paper 49-194, recommended by the AIEE Transformer Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer General Meeting, Swampscott, Mass., June 20–24, 1949. Manuscript submitted November 15, 1948; made available for printing May 2, 1949.

F. J. VOGEL is with the Illinois Institute of Technology, Chicago, Ill., and H. A. HART is with the Armour Research Foundation, Chicago, Ill.

inches would be about 50 kv. The low corona voltages obtained from the washer at the end of the tube and from the hemispherical end emphasize the importance of the terminal design. Although the data do not permit a definite statement, it would seem that the conditions at the flange still determined the performance with the 0.72-inch terminal. Corona at that point prior to flashover confirms this.

In the case of the 1/2-inch terminal, the string distance was still two inches. By extrapolation of the curve for 1/2-inch diameter and 2-inch distance, the expected corona voltage would be of the order of 36 kv.

In applying the law of similitude, it is easiest to calculate new bushing dimensions, smaller by the ratio of the pressures. In other words, if the bushing dimensions were multiplied by 3.4/30, the 2-inch dimension would become 0.225 inch and the rod diameter of 0.5 inch would become 0.057 inch. The corona voltage of this imaginary small bushing at atmospheric pressure, should be the same as that of the full-sized bushing at 3.4 inches of pressure. It is readily seen that the value noted of 7.7 kv is within the range of probability.

The final bushing design was as shown in Figure 1. The terminal was 0.5 inch in diameter and 7/8-inch long. The bushing, for test purposes, was mounted in a container so that the small end could be covered with oil. All possible precautions were taken to eliminate corona on the leads to the bushing. At room temperature and pressure, 23 degrees centigrade and 744 millimeters of mercury, occasional streamers started at the flange at 27 kv, and flashover occurred at 28.5 kv. At room temperature and 3.4-inch mercury pressure, corresponding to 50,000 feet altitude, corona and breakdown occurred simultaneously at about 6.3 kv. This bushing is satisfactory then, since it only had to meet a 5.4 kv test value.

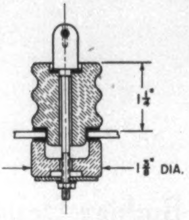

Figure 1. Final bushing design

It would appear at first that there is not too much to gain by electrode design for the low-pressure conditions. This is not quite true. The corona voltage was greatly increased by the addition of a lead from the terminal, as compared to the corona voltage for the terminal alone. Shielding of the flange increases the bushing corona voltage, since it avoids a concentration of stress in air at the edge of the metal. This means that the final bushing design should be a balance between the strength at the terminal and at the flange.

In these tests, the flange or bushing container was connected to ground through a 70-millihenry air-core inductor with a Triumph oscilloscope (sensitivity is 0.09 volts per inch) across the inductor. No additional capacity was used, so that any bushing disturbance would be impressed entirely on the inductance. The question of the point of visual corona against disturbance as noted on an oscilloscope was answered by careful observation in total darkness. It was found that whenever disturbance was present on the oscilloscope, it was possible to see corona at some place in the circuit. The two always occurred simultaneously. However, corona can be hidden behind parts so that it cannot be seen easily, and the oscilloscope then is much more reliable. For example, local corona in the space between the cylindrical terminal and the porcelain occurred when the neoprene gasket was not forced up in that space. This corona showed clearly on the oscilloscope, but could be seen by careful observation only in complete darkness.

Table I. Corona and Breakdown Voltage for Various Bushings and Modifications

Figure 5 represents corona or breakdown voltages for concentric cylinders in air, plotted as a function of inner-electrode diameter and separation between electrodes. The four curves, *1/4"D* to *2"D*, represent the inner-electrode diameter, the data having been taken from several sources. As an example of how these curves might be used, suppose one assumes a 1-inch inner-diameter cylinder and a 3-inch outer-diameter cylinder. The corona or breakdown value for this configuration may be found from the intersection of the *1"D* line and a separation of one inch. This value is seen to be approximately 38 kv.

Also shown in Figure 5 are lines of constant ratio of outer diameter to inner diameter. The usefulness of these lines lies in their giving similar fields along any one constant ratio line which complies with the law of similitude. An example of their use might be as follows:

> Assume that two cylinders have a ratio of outer diameter to inner diameter equal to three, but that these cylinders were large and were tested at the upper region of the curve, say 80 kv. In application it might be necessary to determine the dimensions

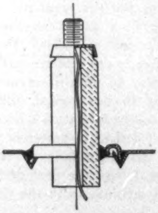

Figure 2. Typical bushing

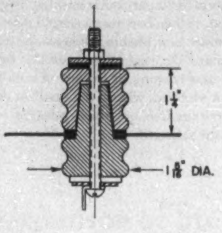

Figure 3. Original bushing design

of concentric cylinders whose field would be the same as the test setup, but whose corona or breakdown value should be about 20 kv. To determine the new cylinder diameters, one travels down the *3/1* constant-ratio line to where it intersects the 20-kv value. From Figure 5 it may be determined that a 0.5-inch inner-diameter cylinder and a separation of 0.5 inch would give the desired breakdown value. The outer cylinder would have a diameter of 1.5 inches.

Another use of the constant-ratio outer-diameter–inner-diameter lines is in applying the law of similitude for reduced-pressure application. Suppose in this example we assume a *4/1* constant-ratio line and a separation of three inches. From Figure 5 this would correspond to a corona or breakdown voltage of 90 kv. If it then is required to find the corona or breakdown voltage of the assumed system at 15 inches of mercury, we may use the *4/1* constant-ratio line, since it automatically gives the same field configuration. At 15 inches of mercury, the 3-inch separation acts the same as a 15/30 × 3 or 1.5-inch separation at 30 inches of mercury. Therefore, if we use the *4/1* line and 1.5-inch separation, we see the new value to be about 45 kv.

Also in Figure 5 are plotted the breakdown curve in air for plane surfaces and the breakdown for an edge of a parallel plate to a plane. It was found that for large spacings, the constant-ratio lines were parallel to the breakdown curve between planes at atmospheric pressure. Of interest is the curve for breakdown of a thin edge to a plane. As may be seen, at some separation less than 0.1 inch, the breakdown of an edge to a plane is about the same as from plane to plane. The dotted portion of the constant ratio lines was not determined experimentally; however, it is expected that the lower portion of these curves must turn up and end finally in the curve for breakdown between planes. The curves are approximately correct for design use.

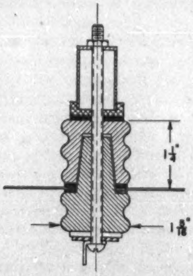

Figure 4. Modified bushing for test

In Figure 5 the experimentally-determined points of corona and breakdown at atmospheric and reduced pressure were used to construct a line of constant ratio for the final bushing design shown in Figure 1. If the values obtained on the final bushing are taken, a line whose constant-ratio value is 8 may be drawn. This can be determined from the string distance of 1.75 inches and the terminal diameter of 0.5 inch; the ratio (2 × 1.75 +0.5)/0.5 follows. Because corona and breakdown occur at approximately the same voltage, the ratio represents a bushing design that is about the smallest obtainable for any given voltage.

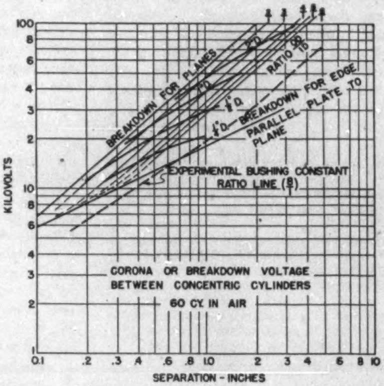

Figure 5. 60-cycle corona voltage for concentric cylinders and final bushing constant ratio line

Having established a ratio line to give a very satisfactory bushing, it is possible, using the law of similitude, to establish the proper bushing dimensions to meet any specified voltage. As an example of the use of the bushing constant-ratio line, we will take a hypothetical problem. A bushing must be corona free at 10 kv rms and at 50,000 feet altitude. From the experimental bushing 8-to-1 ratio line, the separation corresponding to 10 kv is approximately 0.4 inch at normal pressure. Using the law of similitude to find a string distance such that when this new distance is operated at 3.4 inches of mercury it acts as if it were 0.4 inch at normal pressure, we find the equivalent spacing to be 0.4 × 30/3.4, or a 3.5-inch string distance. For a ratio of 8-to-1 the terminal would be one inch in diameter. The ratio of new terminal to old terminal diameter yields the factor by which all bushing dimensions must be multiplied. The final hypothetical bushing dimensions then would be 2.75 inches diameter and 2.5 inches high. A rough sketch of this bushing will show a resulting string distance of about 3.5 inches. The corona voltage of this bushing at atmospheric pressure may be found from the intersection of the bushing constant-ratio (*8/1*) line and a 3.5-inch separation. The voltage corresponding to this point may be seen to be about 55 kv.

In order to apply the law of similitude it must be remembered that the field configuration of the new bushing design must be the same as the one for which the original curve is drawn. To comply with this requirement, the terminal stud and lower portion of the bushing also must be increased in size in the same proportion as the rest of the bushing. Small departure from the original porcelain design should not affect the results too quickly; however, any radical departures in porcelain configuration will affect the field distribution, and expected results may not be met.

From the results of data it may be said that, using Figure 5 as a first approximation, a means of bushing design to avoid corona at either atmospheric or reduced pressure has been presented. It must be realized that the fields associated with a bushing only approach those of concentric cylinders, and as is evident from the final bushing design, the values to be expected for a bushing will be below those for corresponding cylinders. The conditions at the flange are seen to be severe, and it is elimination of stress at this point, especially at atmospheric pressure, that is necessary. By proper proportions it is possible to design a bushing to be corona free up to breakdown. This is borne out by the experimental results stated earlier. If the proper ratio of diameters for a particular bushing is established, it then becomes a simple matter to calculate new bushing dimensions and to estimate the performance of the design. The new bushing, if the law of similitude is not violated, will be the smallest design for corona-free operation relative to its voltage strength.

No Discussion

Comparison of Steady-State and Transient Performance of Servomechanisms

HAROLD CHESTNUT
MEMBER AIEE

ROBERT W. MAYER
NONMEMBER AIEE

A SERIES of charts has been prepared which permit the servo designer to determine readily the kind of servo open-loop transfer function which will yield a desired closed-loop steady-state frequency response or transient response to a step-position input. The open-loop transfer function is expressed in terms of single-gain 2-frequency (or time constant) ratios, and the intermediate attenuation rates so that the servo characteristics are directly interpreted in a form convenient for design purposes.

Study of these charts has indicated to what extent the steady-state and transient characteristics of linear servos may be compared. A number of significant relationships between steady-state and transient performance are discussed.

The performance data which are represented include: the magnitude and frequency at which the maximum of the steady-state response occurs; the magnitude and time at which the peak transient response to a step-function position input occurs; and the settling time and the natural frequency of oscillation of the transient response.

Examples are used to illustrate how the nondimensionalized charts may be employed for synthesizing or analyzing typical servo designs.

Many books and articles have discussed the means whereby a servomechanism system with a known open-loop attenuation characteristic may be analyzed to determine the steady-state frequency response, or to determine the transient response to a step-function input.[1] The converse of this problem, namely, to determine an open-loop attenuation characteristic which will produce a desired frequency response or a transient response to a step function input has been covered only to a limited extent in the literature.[2] However, it is the latter problem which generally confronts the servo designer. He is given a set of specifications involving the steady-state frequency response and/or the transient response to a step input. His problem is to determine the approximate form of the open-loop attenuation characteristic which will provide the desired performance. With this he is in a position to start his more detailed design and to have a fairly definite, although not an absolute, goal toward which to point his design. With the present servo synthesis and design techniques,[3] it is possible for the designer to determine the servo components which will produce the necessary open-loop characteristic.

Since such practical limitations as nonideal components, cost, and weight will probably necessitate deviations from the theoretical open-loop attenuation characteristic initially chosen, it is not essential that the open-loop characteristic be determined with particularly great precision.

It is essential, however to have this open-loop characteristic be reasonably close to the necessary form. In addition, the quantitative effect of changes in the various parameters in terms of the steady-state and transient performance should be understood, so as to indicate a method of refining system design to meet the exact specification requirements.

As a means for meeting the needs just outlined, a series of charts has been prepared which show the steady-state and transient response of ideal linear servomechanisms in terms of the open-loop attenuation characteristics which are necessary to obtain the response. The system parameters which are used to define the open-loop characteristic are described in the next section. The performance characteristics shown on the charts are the following:

$[\theta/D]_m$ = the maximum ratio of output to input of the frequency response

$[\theta/D]_p$ = the peak value of the ratio of output to input for a step function input

ω_m/ω_c = the ratio of the frequency ω_m at which $[\theta/D]_m$ occurs to the frequency ω_c at which the straight line approximation of the open-loop response is zero decibels

ω_t/ω_c = the ratio of ω_t, the lowest frequency of oscillation for a step input to ω_c, the frequency at which the straight line approximation of the open-loop response is zero decibels

$\omega_c t_p = t_p$, the response time from the start of the step function until when $[\theta/D]_p$ occurs, times ω_c, the frequency at which the straight line approximation of the open-loop response is zero decibels

$\omega_c t_s = t_s$, the settling time from the start of the step function until the ouput continues to differ from the input by less than 5 per cent, times ω_c, the frequency at which the straight line approximation of the open-loop response is zero decibels

Indicated in Figures 1(A), (B), and (C) are these various characteristics in terms of the familiar curves of the open-loop transfer function, the frequency response, and the transient response to a step input. In Figure 1(D) are shown how the same characteristics are indicated on the charts merely as a function of the ratio ω_1/ω_c and μ_1. Instead of the more customary curves of Figures 1(A), (B), and (C), only significant performance parameters have been plotted and these

in terms of the open-loop attenuation characteristic which will produce them.

The charts have been prepared on the basis that the system contains a single integrating element so that at very low frequencies the open-loop attenuation characteristic has a slope of 20 decibels per decade. However, as is discussed later, the major factor influencing the performance of the system is the attenuation characteristic in the vicinity of 0 decibels. Hence the charts also may be used to provide worthwhile information on the performance of regulating systems which have zero attenuation rate at low frequencies, as well as torque-motor type systems which have an attenuation rate of 40 decibels per decade at low frequencies, providing the attenuation-frequency characteristics of these systems in the vicinity of zero decibels are comparable to the attenuation characteristic of the system shown on the chart which has the desired performance.

Description of Attenuation-Frequency Characteristics Considered

In Figure 2 are shown the significant parameters which have been used to define the idealized attenuation diagrams for which the steady-state and transient performance have been determined. Although the attenuation characteristic and the block diagram of the system indicate that only series elements have been considered as making up the control system, it is apparent that feed-back loops may be included within the control, providing the resultant attenuation characteristic approaches that for an equivalent system containing only series elements. Basically the attenuation diagram considered is one in which:

1. The attenuation slope is 20 decibels per decade in the vicinity of 0 decibels which gain occurs at the frequency ω_c. This type attenuation characteristic is desirable from the standpoint of providing adequate stability.

2. The attenuation slope increases to 40 or 60 decibels per decade at some higher frequency ω_3 for which the equivalent time constant is T_3, that is, $T_3 = 1/\omega_3$. This may correspond to the presence of the power element time constant or to the condition that is obtained when the loop gain around a feed-back loop falls below unity. In addition, this characteristic may be deliberately inserted to help attenuate undesirable higher frequency input signals.

3. The attenuation rate is 40 to 60 decibels per decade in the region of frequencies from ω_1 to ω_2 for which the equivalent time constants are T_1 and T_2 respectively. Thus,

$$T_1 = \frac{1}{\omega_1} \quad \text{and} \quad T_2 = \frac{1}{\omega_2}$$

4. The attenuation rate is 20 decibels per decade from zero frequency to the frequency ω_1. The system gain at ω_1 is defined as μ_1 on the straight line approximation to the attenuation diagram. The actual gain will be 3 or 6 decibels lower at this frequency, depending on whether the attenuation rate from ω_1 to ω_2 is 40 or 60 decibels per decade.

In some cases, certain of the time constants take on limiting values so that the attenuation diagram appears to have a different form from that shown in Figure 2.

For example, if $T_1 = T_2$, then the slope of 20 decibels per decade extending from low frequencies continues constant until the frequency ω_3. This case is represented on the charts by the data at $\omega_1/\omega_c = 0.1$ and $\mu_1 = 20$ decibels. As another example, consider the case where $T_3 = 0$ so that the 20 decibel-per-decade slope at ω_c is maintained from ω_c on out to infinity. These data are contained on these charts where $\omega_3/\omega_c = \infty$.

Referring to Figure 2, it can be seen that μ_1 in general is not the same as the system gain K which is the value of the gain obtained at $\omega = 1$ if the initial slope from 0 to ω_1 were to be maintained at 20 decibels per decade.

The method which has been employed on the charts to define a given attenuation characteristic is to indicate the nature of the slope between ω_1 and ω_2 as 40 or 60 decibels per decade, and also to indicate the slope between ω_3 and infinity as 40 or 60 decibels per decade. Each chart is then drawn up for a constant value of the ratio ω_3/ω_c. The other parameters used to define uniquely the specific attenuation characteristic are the gain μ_1 in decibels, and the frequency ratio ω_1/ω_c. Since μ_1 and ω_1 are definitely related to the servomechanism specification requirements of a certain maximum error at a specific signal frequency, these are particularly significant parameters from

the viewpoint of system needs as well as of their usefulness to the designer.

The use of the dimensionless ratio ω_1/ω_c as the abscissa serves to broaden the utility of the data while permitting the designer to determine the performance if the system if ω_1/ω_c is already established, or to determine the ω_1/ω_c ratio if the performance of the system is selected as the independent condition for system design.

Although it might appear that broad increments of μ_1 have been chosen for the family of curves plotted against ω_1/ω_c, there are sufficient curves shown to permit fairly straightforward interpolation in most cases.

It should be pointed out that although for convenience purposes the attenuation characteristics are represented by their straight-line approximations, the exact attenuation characteristic has been used in the calculations for the charts.

EFFECT OF VALUE OF ω_c ON FREQUENCY RESPONSE AND TRANSIENT RESPONSE

The preceding section has served to emphasize the importance of the shape of the attenuation-frequency diagram in the vicinity of zero decibels. Although Bode's work has pointed out the importance of this characteristic on stability considerations, its effect on the steady-state and transient response of a servomechanism has not been so clearly emphasized.

Consider the case shown in Figure 3 where two similar attenuation-frequency characteristics are drawn. Both have the same value of μ_1 and both have the same rate of change of attenuation with frequency in the region near 0 decibels; however, the values of the frequencies ω_c', ω_1', ω_2' and ω_3' on the dotted curve are ω_c'/ω_c times higher than the comparable ω_c, ω_1, ω_2 and ω_3 for the solid curve.

It can be shown that for the two characteristics described by Figure 3:

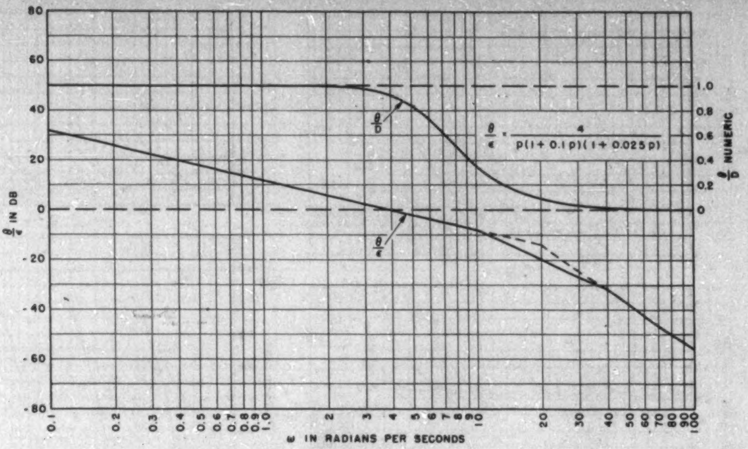
1. The velocity error coefficient for the dotted curve is ω_c'/ω_c times that for the solid curve.

2. The response time and the settling time for the system represented by the dotted curve to the same step-function input are altered by the ratio ω_c/ω_c' times their values for the system illustrated by the solid curve.

3. The ratio of the magnitude of the peak overshoot to the initial transient input is the same for systems represented by the solid and dotted curves.

4. The ratio of the maximum magnitude of the steady-state response to the input sinusoid is the same for the systems represented by the solid and dotted characteristics.

Figure 10. Open-loop transfer function and frequency response for low gain system of Case 1 example



5. The ratio of the frequencies at which maximum output to input ratio of the steady-state response occurs and the frequency at which zero decibels is obtained is the same for systems having the solid and dotted characteristics.

Discussion of Results

From study of the results presented in Figures 12–29, as well as other thoughts which were stimulated by this study, a number of significant relationships were revealed.

EFFECT OF USING PARAMETER ω_1/ω_c FOR ABSCISSA

In Figure 4 are shown a number of open-loop attenuation characteristics in which μ_1, ω_c, and ω_2 are held constant and the ratio ω_1/ω_c is allowed to vary. It is evident that as the frequency ω_1 is increased, the frequency ω_2 also must be increased and therefore is more nearly equal to ω_c. For the increased ω_2, the section of 20 decibel-per-decade slope in the vicinity of 0 decibels is reduced and it would appear from a qualitative point of view that a less stable system would result, that is, one having a higher value of $[\theta/D]_m$ (steady-state) and a higher value of $[\theta/D]_p$ (transient). This result is indicated quantitatively in the curves of $[\theta/D]_m$ and $[\theta/D]_p$ as a function of ω_1/ω_c for μ_1 and ω_c constant.

It might appear that fairly broad interpolation would be required to obtain performance figures at values of μ_1 other than those specifically calculated. Actually the θ/D values for values of μ_1 greater than 40 seem to be determined largely by the values of ω_2, so that the effect of going to higher values of μ_1 has the effect of reducing ω_1/ω_c to a lower value for the corresponding servo performance.

Reference to Figure 29 which has the same ordinates as Figure 24 but which has ω_2/ω_c as its abscissa, indicates that there can be a close dependence of the transient and steady-state on ω_2/ω_c, and that there may be a relatively small effect on the system performance for changes of μ_1 as long as the value of μ_1 is large, say 60 decibels or greater.

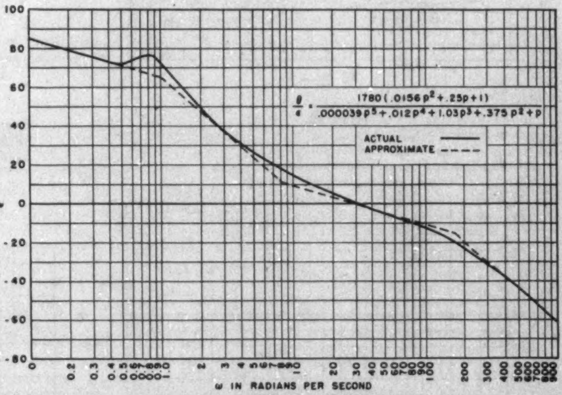


Figure 11. Actual and approximate open-loop transfer function for high gain system of Case 2 example

COMPARISON OF MAXIMUM STEADY-STATE VALUE OF OUTPUT-INPUT RATIO $[\theta/D]_m$ TO PEAK VALUE OF TRANSIENT OUTPUT-INPUT RATIO $[\theta/D]_p$

Study of the data presented on the upper portions of Figures 12 to 29 reveals that the maximum steady-state value $[\theta/D]_m$ generally exceeds the peak value of the transient $[\theta/D]_p$ or most values of ω_1/ω_c although this is not universally true. It is only for systems which have a low value $[\theta/D]_m$ that is, less than 1.25 that $[\theta/D]_p$ may exceed $[\theta/D]_m$. For these systems the maximum value of both the steady-state or transient is low, and

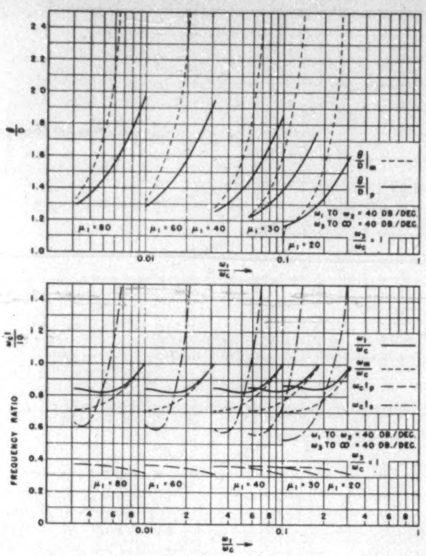

Figure 12

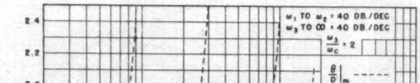

Figure 13

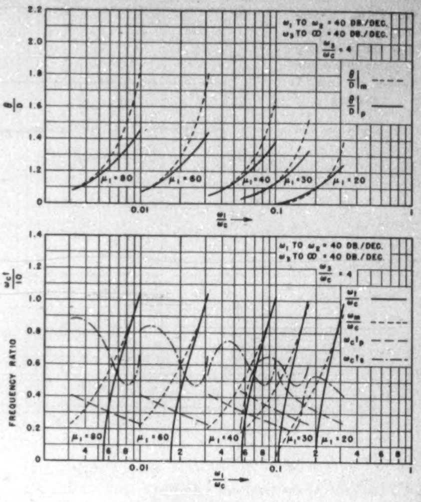

Figure 14

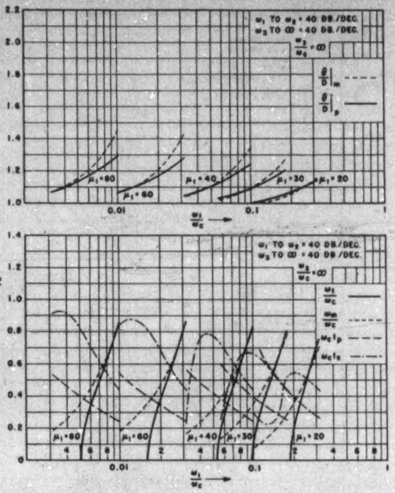
Figures 12 to 21. Comparison of steady-state frequency response characteristics and transient response following a step-function of input as a function of ω_1/ω_c

Figure 15



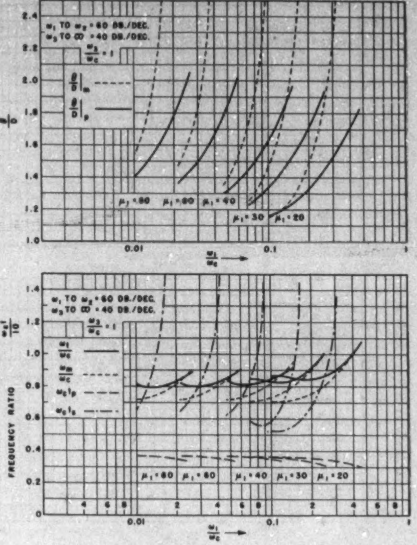


Figure 16 (above), Figure 17 (right). Comparison of steady-state frequency response characteristics and transient response following a step-function of input as a function of ω_1/ω_c

the transient peak seems not to exceed the steady-state maximum by more than 5 per cent of the input in any case. Systems such as these are exceptionally stable ones for which the degree of damping is fairly high although the systems are not quite critically damped. It will be recalled that a highly damped quadratic system of this sort is capable of some overshoot to a step-function transient although the steady-state frequency response has a maximum value of 1.0 or only slightly greater.

The value of $[\theta/D]_m = 1.25$ appears to be one at which $[\theta/D]_m$ for a system is equal to or somewhat in excess of $[\theta/D]_t$. Since $[\theta/D]_m = 1.3$ is a design figure which is frequently used, it is convenient to know that $[\theta/D]_p$ will be less than this amount for this case. Although by proper choice of design the value of $[\theta/D]_p$ may be reduced with the value of $[\theta/D]_m$ held constant at 1.3, the improvement possible is limited to a few per cent.

This comparison of the maximum steady-state and transient magnitudes has revealed quantitatively a condition long realized qualitatively by practical designers, namely, the use of the steady-state rather than the transient basis for design is quite satisfactory since a system having a low maximum value for its steady-state response also will have a low overshoot for its transient response.

COMPARISON OF FREQUENCY ω_m AT WHICH $[\theta/D]_m$ OCCURS TO ω_t, THE LOWEST FREQUENCY OSCILLATORY TERM OF THE TRANSIENT RESPONSE

The figures presented on the lower portion of Figures 12 to 28 compare plots of ω_m/ω_c and ω_t/ω_c for the systems having the $[\theta/D]_m$ and $[\theta/D]_p$ values shown in the upper portion of these figures.

As such these data may be used for the purpose of rapidly determining the frequency characteristics of a contemplated design. Since, as is generally the case, the actual frequency of ω_m is given as a specification requirement, the ω_m/ω_c ratio is useful in establishing the frequency ω_c which will be required to obtain the value of ω_m desired.

In addition these frequency data presented in the charts can be used to indicate certain trends in performance which result from the selection of one or another design, both of which may have comparable values for $[\theta/D]_m$ or $[\theta/D]_p$. If ω_m/ω_c and ω_t/ω_c be compared for the same system, then a direct comparison of ω_m and ω_t can be made. From such a comparison the following generalities are indicated:

Effect of ω_3/ω_c

Systems in which $1<\omega_3/\omega_c<4$ correspond to fairly oscillatory systems with little damping. For these systems the lowest frequency of transient oscillation ω_t is greater than the frequency ω_m at which the steady-state response is a maximum. The variation of the values of ω_t/ω_c and ω_m/ω_c is fairly small and the values of each are about 1.0. For systems having higher values of the ω_3/ω_c ratio, that is, $\omega_3/\omega_c>4$, ω_m exceeds ω_t. There can be a wide variation of both the values of ω_t and ω_m as ω_1/ω_c is changed. The values range from about one for each when ω_1/ω_c is large for a given μ_1, that is, fairly oscillatory systems, to zero for ω_t at low values of ω_1/ω_c when the systems are so stable as to have all real roots. The oscillatory and stable systems correspond to values of ω_2/ω_c which are near 1.0 and near 0.1 respectively.

Effect of Change in μ_1

The shape of the ω_t/ω_c and ω_m/ω_c curves for a constant μ_1 and over a range of ω_1/ω_c bears a close resemblance to these same curves for a different μ_1 but the same ω_3/ω_c. This tends to indicate that if ω_3/ω_c and ω_2/ω_c are fixed and μ_1 and ω_1 alone are changed, the changes in ω_m/ω_c and ω_t/ω_c are not great. However, it is evident from the curves that the effect of reducing the gain μ_1 is to increase the ω_m/ω_c and ω_t/ω_c ratio.

Effect of Attenuation Slope ω_3 to Infinity

For systems in which the attenuation slope from ω_3 to infinite frequency is 60 decibels per decade rather than 40 decibels per decade, the values of ω_m/ω_c are higher. That is, the frequency at the steady-state maximum is more nearly that of ω_c when a 60 decibel-per-decade slope at the higher frequencies is employed. From the point of view of decreasing the transmission of the system at higher frequencies, this appears

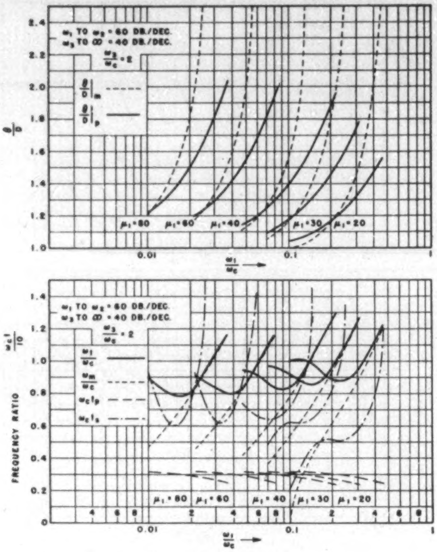

Figure 18

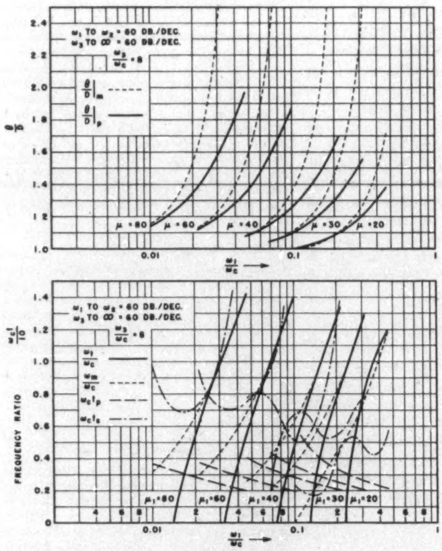

Figure 19

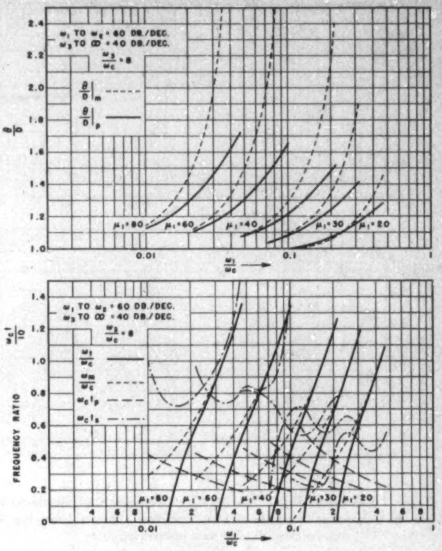

Figure 20

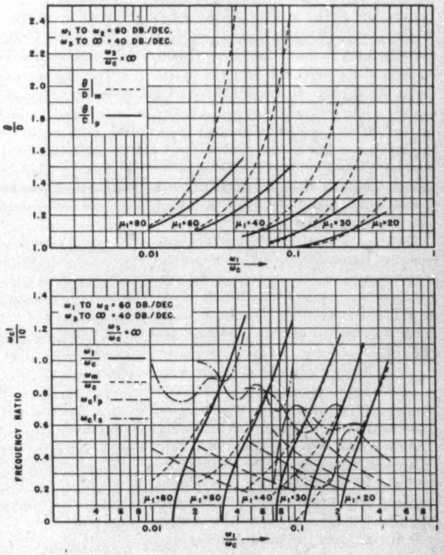

Figure 21

Figures 12 to 21. Comparison of steady-state frequency response characteristics and transient response following a step-function of input as a function of ω_1/ω_c

desirable but transient considerations which are discussed in the following section may be of greater importance.

TIME AT WHICH PEAK OVERSHOOT OCCURS

Reference to Figures 12 to 28 indicates that for the lower values of ω_2/ω_c, in the range from $1 < \omega_2/\omega_c < 4$, $\omega_c t_p$ is approximately equal to three and is relatively unaffected by changes in μ_1 or ω_1/ω_c for a constant value of ω_c. However, since the ordinate of these curves is $\omega_c t_p$ the value of t_p, the elapsed time from the application of a step function until the peak overshoot, is inversely proportional to ω_c. Therefore, it is primarily by increasing ω_c that the time t_p can be reduced.

When $\omega_2/\omega_c \leq 8$, $\omega_c t_p$ tends to vary over a wider range and to decrease as ω_1/ω_c takes on larger values with μ_1, ω_c, and ω_2 constant. This may be verified in a qualitative way by reference to Figure 4 where as ω_1 takes on increasing values, the actual gain of the system is increased for the frequencies lower than ω_2 and a shorter time should be required for the initial step displacement to be reduced to zero. Figures 5 and 6 comparing the actual transient response as a function of time for constant values of μ_1, ω_c and ω_2 indicate in a quantitative fashion the decrease in time required for the higher gain, lower ω_1/ω_c systems to reach their transient peak although the peak attained is higher.

SETTLING TIME AFTER WHICH TRANSIENT OVERSHOOT REMAINS LESS THAN 5 PER CENT OF ORIGINAL DISTURBANCE, t_s

If the magnitude of the peak overshoot can be made less than the allowable limit, then the time t_p alone is of interest. However, when the initial overshoot exceeds the desirable operating value of the output, the performance may still be satisfactory if the succeeding overshoots can be brought within acceptable limits within an allowable length of time.

The acceptable error limit which was selected for purposes of this study is ±5 per cent from the desired step input. Since most high performance servo systems tend not to be linear for large displacements, the step input for which this analysis is valid is likewise small. Consequently 5 per cent of this magnitude is probably a small enough error to be acceptable.

No simple over-all statement can be made concerning the shape of the $t_s\omega_c$ characteristics. There are certain trends which are present that are worthy of mention however, and can be readily appreciated by reference to Figures 5 and 6. It will be noted that as the values of ω_1/ω_c decrease, the amplitude and the apparent frequency of oscillation also decrease. The decrement rate of the exponentially decaying term also changes with ω_1/ω_c so that the time at which the overshoot is 5 per cent is subject to rather large fluctuations of the order of one-half the period of oscillation.

It should be noted that only five data points were used to construct each curve on the charts so that it was not possible to determine the exact value of ω_1/ω_c where the transient no longer exceeded 1.050 to 0.950. Since the ±5 per cent figure represents an arbitrary value, and since slight changes in the system parameters will alter the actual transient response somewhat, smooth curves were drawn to indicate the $\omega_c t_s$ function. These tend to minimize the abruptness of the transition of the $t_s\omega_c$ response from one-half cycle to the next half cycle of oscillation.

Figure 5 shows the transient response of a system in which the initial peak in all cases is greater than 5 per cent. As ω_1/ω_c is decreased from its highest value, $\omega_c t_s$ first decreases as the peak overshoot decreases and the decrement rate remains fairly high. As ω_1/ω_c further decreases, the frequency of oscillation is lowered and the decrement rate is also decreased; hence, the initial overshoot is maintained for a longer period. Therefore $\omega_c t_s$ is increased again as ω_1/ω_c is further reduced.

Curves 1, 2, and 3 of Figure 6 indicate a continuation of the trend noticed in Figure 5 toward higher values of $\omega_c t_s$ as ω_1/ω_c is decreased. However as ω_1/ω_c is further decreased, the peak overshoot falls below 1.05, and for curve 4 the output remains within 5 per cent of the input after it reaches $\theta/D = 0.95$ at $\omega_c t = 2.35$. A further decrease in the ω_1/ω_c ratio as shown by curve 5 causes the system to be more heavily damped and the time required to get to $\theta/D = 0.95$ is again increased.

For a system having μ_1, ω_c, and ω_2 fixed, the time after which the error to a step-position input remains less than a small amount can be decreased only so far by decreasing ω_1. A further decrease in ω_1 merely causes the system to become too sluggish. Quantitative data are provided by Figures 12 to 28 which indicate whether an improvement in system performance will be realized by such a decrease in ω_1/ω_c.

The beneficial effect of increasing the frequency ω_c mentioned in conjunction with t_p also is realized for t_s since the time ordinates on Figures 12 to 28 are $\omega_c t$.

USE OF FIGURES 12 TO 28 FOR SYSTEMS OTHER THAN THOSE HAVING A SINGLE INTEGRATING ELEMENT IN THE CONTROLLER

Although the results presented in Figures 12 to 28 are valid only for systems having the attenuation diagrams specified, they are also of considerable use for predicting the performance of systems having quite different attenuation-frequency characteristics at low frequencies, but which have identical attenuation characteristics for frequencies for which the open-loop characteristic is in the vicinity of zero decibels and for all higher frequencies. Figure 7 shows three such systems while Figure 8 indicates the frequency response of each. Type "0" indicates a system which requires an error to obtain a constant output position and is characteristic of regulating systems. Type "1" indicates a system in which a constant error produces a constant output velocity and represents the type of system used extensively for high performance position controls. Type "2" indicates a system in which a constant error produces a constant output acceleration and represents a type system less frequently employed. It is evident that for these three systems there is little to choose from as far as the frequency response is concerned. The type "0" system has a slightly lower maximum value than that of the type "1" system, while the type "2" system has a slightly higher maximum value than the type "1" system. It would appear that this relationship between the magnitude of the response of systems of these various types is fairly general although it is not probable that the frequency of the maximum of the frequence response will be the same for each in the general case.

Figure 9, in comparing the transient response to a step function of these three seemingly different systems also reveals that there is a close comparison between them. It is doubtful that this close a comparison will be obtained for the more general case, where the attenuation characteristics are dissimilar until the gain is lower than that for the three systems considered. However, the possibilities of the performance results for a type "1" system in providing a ceiling indication for the type "0" system and a lower limit value for the type "2" system is apparent.

For type "2" systems in which the initial attenuation rate is 40 decibels per decade at very low frequencies followed by a section of 20 decibel-per-decade attenuation rate in the region of ω_c, the question arises as to which values of

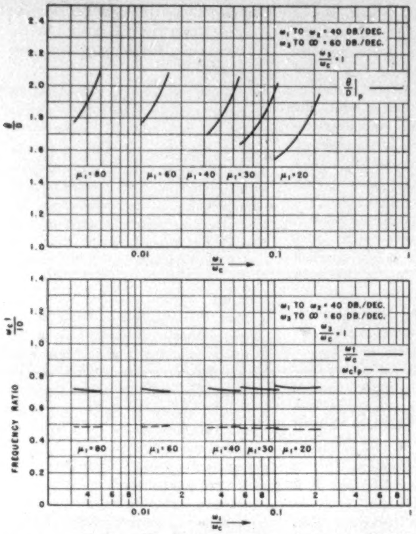

Figure 22. Transient response following a step-function of input as a function of ω_1/ω_c

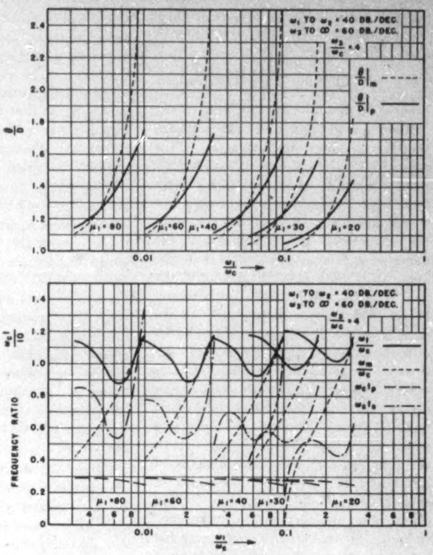

Figure 24

Figures 23 to 28. Comparison of steady-state frequency response characteristics and transient response following a step-function of input as a function of ω_1/ω_c

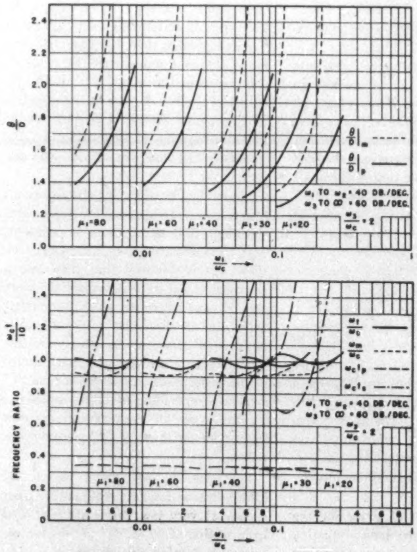

Figure 23

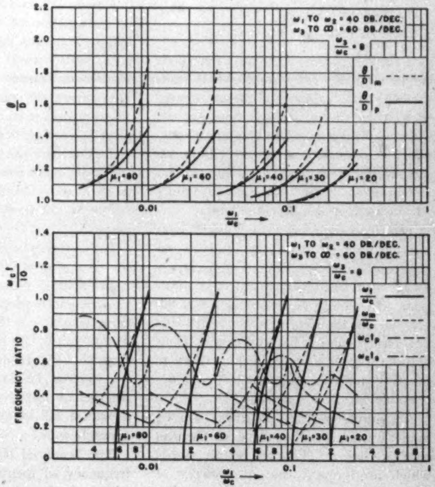

Figure 25

μ_1 and ω_1/ω_c should be used with which charts. The charts to be used are those for which the attenuation rate from ω_1 to ω_2 is 40 decibels per decade and those for which the proper value of ω_3/ω_c and attenuation rate from ω_3 to infinity are obtained. Select the $\mu_1=80$ decibels characteristics and use the value of ω_1 determined at $\mu_1=80$ decibels for the actual transfer function attenuation characteristic; the values of the performance parameters indicated should most closely approximate those actually obtained for the 40 decibels per decade, type "2" system.

EFFECT OF HAVING NONMULTIPLE BREAKS TO OPEN-LOOP ATTENUATION CHARACTERISTICS

In the interest of presenting a fairly complete picture of the performance of representative servo systems with a limited number of charts, it was considered necessary not to include systems in which there are intermediate breaks in the attenuation diagram. For example, the ideal cases represented in the charts by multiple breaks where in the open-loop diagram the attenuation rates change abruptly from 20 to 60 decibels per decade or vice versa are generally realized in practice by two adjacent breaks so that there is an intermediate section of 40 decibels per decade. Fortunately design methods are such that frequently this 40 decibel-per-decade attenuation section is limited to a short range of frequencies. In this way the attenuation and phase shift of the system at some frequency remote from this range of frequencies is essentially the same whether multiple breaks occur for example, at the frequency ω_1, or two separate breaks occur at somewhat higher and somewhat lower frequencies than ω_1. As a general rule,[3] two different but neighboring time constants T_a and T_b may be replaced by two equal time constants of value T_{ab} which are defined as

$$T_{ab}=\sqrt{T_aT_b}$$

This approximation may be verified in a qualitative fashion by a comparison of the terms

$$(1+T_ap)(1+T_bp)=1+(T_a+T_b)p+T_aT_bp^2$$

and

$$(1+T_{ab}p)^2=1+2\sqrt{T_aT_b}p+T_aT_bp^2$$

The difference between the two is that the coefficients of the p term are T_a+T_b and $2\sqrt{T_aT_b}$ respectively. When $T_a=T_b$ the ratio of $(T_a+T_b)/2\sqrt{T_aT_b}$ is 1.0; when T_a is as much as four T_b, the ratio of $(T_a+T_b)/2\sqrt{T_{ab}}$ is only $5/4=1.25$ and the maximum variation between the two amplitude characteristics is only about 2 decibels.

The intermediate frequency ω_{ab} corresponding to the intermediate time constant T_{ab} can be located graphically merely by extending, until they intersect, the sections of 20 and 60 decibel-per-decade slope on either side of the 40 decibel-per-decade slope noting the frequency at the intersection. If this frequency is used for an equivalent ω_1, ω_2 or ω_3 as the case requires, reasonably good agreement should be realized between the actual results and those indicated by the charts.

It is of interest to note that transfer functions having quadratic terms with complex factors also may be represented by two equal factors for purposes of using the charts. Thus, approximately

$$(1+2\zeta T_p+T^2p^2)\simeq(1+T_p)(1+T_p)$$

which yields the same value as that given by T_{ab} in the preceding discussion.

CHOICE OF ATTENUATION RATES BETWEEN ω_1 AND ω_2, AND ω_3 AND INFINITY

For systems in which the parameters μ_1, ω_1, and ω_3 are fixed and the attenuation rate from ω_1 to ω_2 alone is a design choice to be made, the use of a steeper slope (60 decibels per decade) produces lower values of $[\theta/D]_m$ and $[\theta/D]_p$ than use of the less steep (40 decibels per decade) slope. However, it will be noticed that despite the lower initial transient peak for the 60 decibel-per-decade slope, the time required for the transient to settle to 5 per cent of the magnitude of the step input is generally somewhat greater for this case. Hence the choice is not clearcut for all cases and the relative importance of maximum magnitude of transient or setting time must be considered.

In the case where all other system parameters are chosen but the slope of the open-loop attenuation characteristic between ω_3 and infinity, the use of an attenuation rate of 60 decibels per decade rather than 40 decibels per decade increases $[\theta/D]_m$ and $[\theta/D]_p$. In addition the time for the transient error to settle to 5 per cent of its original value also is increased somewhat by use of the steeper slope.

It should be noted however that use of the higher attenuation rate may be advantageous in eliminating undesirable noise signals in the higher frequency region of the spectrum. In a sense the inability of the 60 decibel-per-decade system to respond rapidly to transient inputs may not be a liability for, in so doing, the system also is made insensitive to the extraneous high frequency nois signals as well.

Examples

The information presented in Figures 12 to 28 is useful either for purposes of analysis, that is, determining the response of systems already designed or for purposes of synthesis, such as determining what sort of system will be required to do a specified job. Typical examples of each of these uses are shown in the following:

CASE 1. CHARTS USED FOR SYSTEM ANALYSIS

Determine approximately the value of the maximum value of θ/D and the frequency at which it occurs, and the magnitude of the peak overshoot to a step-function input and the time when it occurs for a system having the transfer function.

$$\frac{\theta}{\epsilon}=\frac{4}{p(1+0.1p)(1+0.025p)}$$

which is drawn on Figure 10. Also drawn on Figure 10 for purposes of check is the frequency response from which $[\theta/D]_m$ and ω_m/ω_c are found to be 1.00 and 0 respectively.

From Figure 10 the information necessary to specify the various parameters for use of the charts can be obtained. Thus

$\omega_c=4$
$\mu_1=20$ decibels
$\omega_1=0.4\quad(=\omega_2);\quad \frac{\omega_1}{\omega_c}=0.1$
$\omega_3=10$ and $\omega_3/\omega_c=2.5$ if slope is 40 decibels per decade, ω_3 to infinity

or

$\omega_3=20$ and $\omega_3/\omega_c=5.0$ if slope is 60 decibels per decade, ω_3 to infinity

Since no section of either 40 or 60 decibels per decade occurs before zero decibels, the charts for which the attenuation rate from ω_1 to ω_2 is 40 decibels per decade may be used with the data obtained at $\mu_1=20$ and $\omega_1/\omega_c=0.1$.

Two alternatives present themselves for selecting the attenuation rate from ω_3/ω_c to infinity. By choosing this rate to be 40 decibels per decade and $\omega_3/\omega_c=2.5$, a system performance somewhat more optimistic than will be actually realized will be determined. By choosing the attenuation rate to be 60 decibels per decade and using a value of $T_3=T_{ab}$, then $\omega_3/\omega_c=5$ and more realistic values of system performance should be determined. Table I is a comparison of the values of the desired performance quanti-

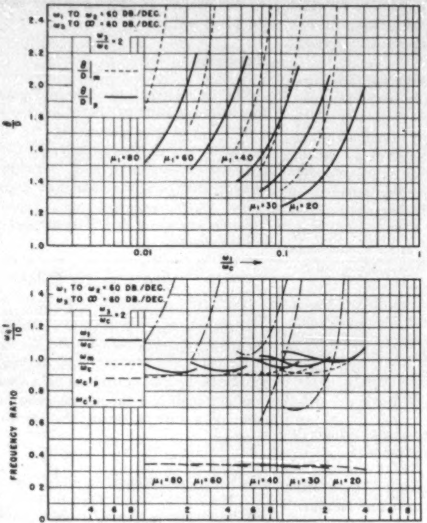

Figure 26 (above), Figure 27 (below)

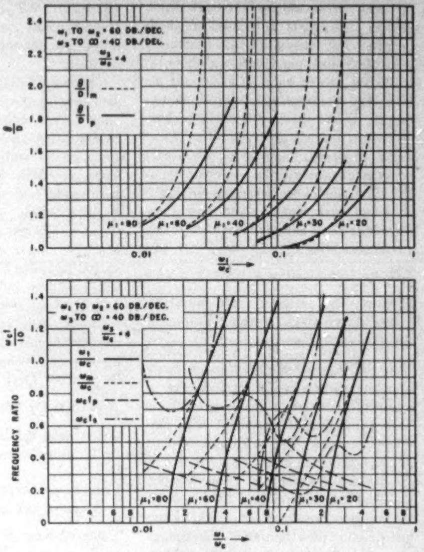

Figure 28

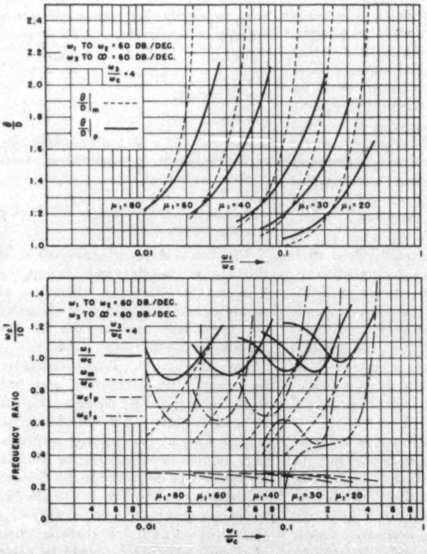

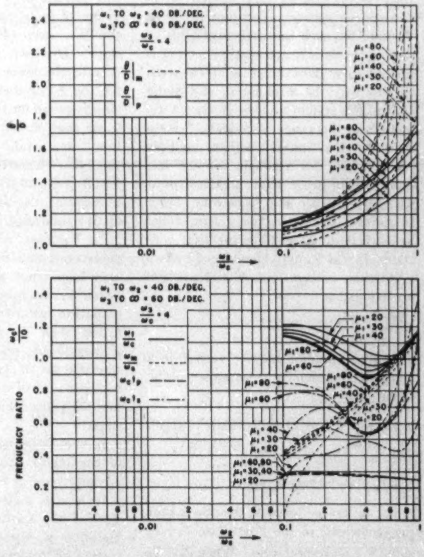

Figures 23 to 28. Comparison of steady-state frequency response characteristics and transient response following a step-function of input as a function of ω_1/ω_c

Figure 29. Comparison of steady-state frequency response characteristics and transient response following a step-function of input as a function of ω_2/ω_c

Table I

	$\frac{\omega_3}{\omega_c}=2.5$ Figures 13, 14	$\frac{\omega_3}{\omega_c}=5.0$ Figures 24, 25	Actual System Performance
$[\theta/D]_m$	1.00	1.00	1.00
ω_m	0	0	0
$[\theta/D]_p$	1.02	1.02	1.04
t_p	0.75	0.75	0.74

ties based on these two assumptions as well as the actual values obtained by direct calculation. It is evident that these results are essentially independent of the method used to obtain them, that is, whether the 40 or 60 decibels-per-decade charts are used.

Case 2. Comparison of System Performance Obtained From Charts and Actual System Calculations

For the high gain system shown in Figure 11 in which the solid line indicates the actual open loop transfer function and the dotted lines indicate the straight line approximations to this transfer function, find the values of $[\theta/D]_m$, $[\theta/D]_p$, ω_m, and t_p.

The information necessary to determine the proper charts and performance is found from Figure 11 to be

$\omega_c=28$ radians per second
$\omega_1=1$ radian per second
$\mu_1=65$ decibels
$\omega_3'=168$ radians per second
ω_1 to $\omega_2=60$ decibels per decade
ω_3' to $\infty=60$ decibels per decade
$\frac{\omega_1}{\omega_c}=0.035$
$\frac{\omega_3'}{\omega_c}=6.00$

It will be noted that the value of ω_3' is an equivalent value and is obtained by use of approximate methods described previously. Hence Figures 27 and 28 must be used. In Table II is a comparison of the desired performance quantities as obtained from the charts with the actual values obtained by direct calculation.

Charts Used for System Synthesis

It is desired to determine an open-loop attenuation frequency characteristic for which the maximum value of the frequency response is 1.4 or less and occurs at frequency greater than 3 cycles per second. The ratio of output to error for a sinusoidal input of 1 radian per second should be at least 500. The attenuation rate for frequencies in excess of 120 radians per second will probably be 60 decibels per decade.

From the foregoing data, the following preliminary values of design parameters may be selected:

$\omega_m=3\times 2\pi=18.8$ radians per second
$\mu_1=60$ decibels (which produces the proper actual gain at ω_1)
$\omega_1=1$ radian per second
$\omega_3=120$ radians per second

Since the attenuation rate from ω_3 to infinity is to be 60 decibels per decade and since high system performance is desired, Figures 26 to 28 will be used. Figure 27 for which $\omega_3/\omega_c=4$, shows that for $\mu_1=60$ and $[\theta/D]_m=1.4$, $\omega_1/\omega_c=0.033$ and $\omega_m/\omega_c=0.68$. For these conditions then, $\omega_c=18.8/0.68=27.6$ radians per second. This indicates that a value of $\omega_c=30$ can be used and the values of ω_1 and ω_3 above are satisfactory. The value of ω_m obtained is $0.68\times 30/2\pi=3.25$ cycles per second and is greater than the minimum allowable value. From this it appears that the specifications have been met.

Table II. Comparison of System Performance Obtained From Charts and Actual System Calculations

	Performance from Figures 27, 28	Actual System Performance
$[\theta/D]_m$	1.56	1.57
ω_m	20	20
$[\theta/D]_p$	1.42	1.40
t_p	0.1	0.1

Therefore, an open-loop attenuation characteristic for which the system performance is satisfactory is

$$\frac{\theta}{\epsilon}=\frac{1{,}000\,(1+0.17p)^2}{p(1+p)^2(1+0.0083p)^2}$$

Since the most convenient means for obtaining this transfer function practically may not be such that the exact time constants indicated before are realized, it is probably not worthwhile to determine the transfer function more precisely from the charts.

Instrument Inaccuracies in Feed-Back Control Systems with Particular Reference to Backlash

H. TYLER MARCY
ASSOCIATE AIEE

MORRIS YACHTER
NONMEMBER AIEE

JEROME ZAUDERER
NONMEMBER AIEE

ALTHOUGH the techniques of analysis and synthesis of feed-back control systems have been developed to a high degree of usefulness, there is continuing need for expanding and improving them. It is the object of this paper to investigate some of the problems of component specification within the feed-back control system. It is obvious that there is a direct relation between most economical component procurement, or production, and optimum specification of their required physical characteristics. But just how good, or how powerful, the components must be is not often simply determined from the requirements of over-all system performance. This problem is particularly important in designing feed-back control systems because of the large percentage of high quality, expensive equipment.

In feed-back control systems, the components may be thought of as a part of the direct, or forward path, the feed-back path, or the comparator as illustrated in Figure 1. Broadly speaking, the function of components in the direct path is amplification of signal level and power with selected frequency response characteristics. On the other hand, the function of the components in the feed-back path and in the comparator is primarily measurement.

The problems of specification of these two general types of components are likely to differ. In more complicated systems, having multiple feed-back paths and cascades of assemblies which themselves employ feed-back techniques, there exist a function of the component in its own local environment and a function of the assembly in which it is incorporated.

A study of measuring equipment as used in feed-back control systems is the primary concern of this paper. The nature of instrument inaccuracies will be considered and cataloged according to type. An attempt will then be made to determine the effect of the specific instrument inaccuracies on the accuracy of the regulating system.

Unfortunately, in considering those threshold operating points of components which determine just how good they are, the problem of analysis does not always remain mathematically simple and clear-cut. Here, use is made of analog techniques in obtaining solutions from an electronic differential analyzer and use is made of mathematical techniques for nonlinear mechanisms.

General Discussion of Instrument Characteristics

When an instrument is applied to an experiment or a process for purely measuring purposes, the resulting data are evaluated differently than when the same instrument is used as a part of a regulating system. The accuracy of an experimental determination of, say, an explicit relation between two variables is more often obtained by a "fairing" of the data[1] through the device of measuring for an appropriate number of settings of the independent variable. In experiments, accuracy of measurement can be improved sometimes by such techniques as unidirectional approach of the measuring point with the variable setting mechanism and by the use of check calibration. When an instrument is used in a regulating system, its ability to command cannot necessarily be compared with its ability to measure in an experiment, because it will be making continuous determinations without special attention from an operator.

The exact effect of an instrument inaccuracy upon the regulating system of which it is a part is observed to be dependent upon the cause of the inaccuracy. For example, the effect of backlash in a position indicator results in a different sort of system error than the effect of random noise in the same indication. It would seem, therefore, that an organization of instrument inaccuracies into types would be prerequisite to a study of their effect of regulating systems.

If the controlled quantity of an automatically regulated process be assigned the mathematical symbol θ_0, then this symbol has a particular physical meaning such as temperature, angle, and so forth. Almost without exception, the controlled quantity is measured, and an equivalent but not like quantity is used to initiate the control action. The instrument used to obtain such an equivalent quantity, such as volts for temperature, is characterized by its ability to produce a known correspondence between its actuating quantity and its output quantity. These characteristics may be classified briefly as describing either internal characteristics in the instrument (such as sensitivity, static and dynamic accuracy, internal passive parameters, or internal active sources) or environmental conditions (such as the relative loading of instrument on the actuating quantity or vice versa, and other physical effects

which the instrument sees in addition to the real actuating quantity).

For the subject at hand the classical separation of instrument characteristics into sensitivity and accuracy is expanded to include sensitiveness to extraneous sources of excitation as additional items measured. The concept of sensitivity is more applicable if associated with that particular part of the instrument which does the converting. In a thermocouple this would be the hot junction itself and would not include the thermocouple well. The cold junction is a second convertor or primary detector within the same instrument.

The prevailing concept of accuracy of instruments needs to be elaborated for the purpose of the present study. The output from a measuring instrument has a value corresponding to the measured quantity.[2] The output may be in the form of a scale reading, a pen position, or any other quantity such as a voltage. There may be, in fact, more than one output in a multi-purpose instrument which indicates and controls. A functional division of an elementary instrument is sketched in Figure 2 after the manner of Kinnard.[3]

A classification of types of instrument inaccuracies which was helpful in the present study of their effect on feed-back control systems is given in Table I. Some common sources of inaccuracy are itemized as examples. A distinction is made between mechanism errors,[4] which are the subject of Table I, and theoretical errors in the primary element, which are not considered here. Since the effect of an energy source on a feed-back control system is different from the effect of a passive circuit, a distinction is made in Table I between these two types of inaccuracy. Another major division is whether the inaccuracy cause is self-contained in the instrument or is environmental.

That the linear analytical techniques thus far developed for feed-back control systems can be widely used in a study of instrument inaccuracies is shown by the number of items of Table I which can be studied by these means, provided none of the nonlinear causes of error are also present. There are preferred techniques of analysis for certain of the items. Whereas the effect of cascaded impedance with the instrument source causes difficulties that can be studied by transient analysis or frequency response methods, on the other hand the random source of the inaccuracy must be treated by statistical means and probably can best be studied by determinations of the rms of regulating error for typical input conditions.[6] An attempt has been made to indicate the technique best applicable.

It is the nonlinear problem that plagues the designer because of his relative inability to assess the importance of such effects. In order to predict how a given system is going to work, at the present state of the art, it is seemingly necessary to either build an experimental prototype of the regulated equipment, use analog or other simulating devices, or just hope for the best. While these procedures always may be used, it would be well to ascertain by some other means what approximate conditions can be expected. It would seem to the authors that the proper job of the professional society is to encourage systematic collection of data and distribution of this information. In this pres-

Table I. An Organization of Instrument Inaccuracies and Suggested Means of Analyzing Their Effect

Examples of Specific Inaccuracies	Suggested Means of Analysis
Passive Sources of Error Due to Internal Defects	
Nonideal transfer function of linear networks	
Band-pass of electronic or other amplifier used as intermediate means	Added element to conventional servo theory
Presence of energy storage elements in cascade with the primary detector	Added element to conventional servo theory
Impedance loading on primary detector or other elements of system	Alters element characteristics in way predictable by circuit theory
Nonlinearities in elements	
Backlash Spring or magnetic hysteresis	Prototype, analogy computer or by approximate analysis.[6]
Breakaway and coulomb friction (or dimensional equivalent)	Analysis by phase plane techniques[8]
Variation from linearity of springs, bridge circuit, and so forth	Incremental treatment, analogy computer or prototype, point by point numerical solution
Saturation	Analysis by phase plane techniques[8]
Nonideal viewing of measured quantity by primary detector	
Measurement at discrete intervals	Analysis of pulsed data systems
Equivalent of scanning time function with square instead of unit impulse	Superposition
Passive Sources of Error Due to Environment	
Effect on measured system by primary detector	
Catalytic effects (accelerating and deterrent)	Experimental
Impedance loading	Circuit theory
Alteration of process as, for example, change of fluid flow from laminar to turbulent in the vicinity of a probe	Experimental
Effect of measured system on primary detector	
Contamination, as for example a gradual destruction of platinum-rhodium thermocouple	Long-time change of system characteristics
Impedance loading on primary detector, such as conduction errors in thermocouple installation, and shielding	Experiment or circuit theory
Internal Active Sources of Error	
Purely random signals	
Thermal noise due to molecular agitation	Statistical analysis of variable, autocorrelation functions
Atmospheric fading as in radar systems	
Quadratic and Harmonic signals	
Minimum transfer signals	Spurious input in conventional servomechanism theory[7]
Imperfect optical transmission	
External Active Sources of Error	
Environmental	
Thermal effect on parameter constants and on contact potentials	Can probably be treated as long-time change of system characteristics; alternatively involves nonlinear analysis or resort to analog techniques
Pressure effect on primary detector and on parameters	
Inertial reactions	
Secondary sensitivities of primary element	
Stray fields	Spurious input in conventional servomechanism theory,[7] except when saturation effects are introduced[8]
Cross-talk as in quadrature sensitivity of linear accelerometer	

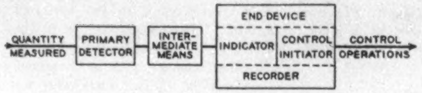

Figure 2 (above). Functional division of an elementary instrument

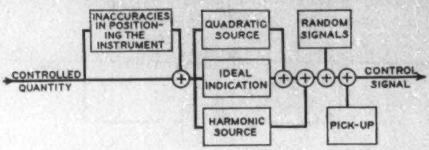

Figure 3 (right). Representation of some inaccuracies of a null instrument

ent study, backlash in the instrument has been a principal object of experimental study. Other investigators have touched on this and some of the remaining problems.[10]

Nonlinear systems which can be described to within reasonable accuracy by a single degree of freedom, can be studied by the so-called phase-plane method of analysis, first introduced by Poincare.[12] This is particularly true for an on-off system with, say, constant displacement or constant velocity input; that is, for a system which is described by a linear differential equation but with discontinuous coefficients, the discontinuities occurring along certain curves in the phase plane, usually not known explicitly. Such a system, with idealized backlash in output measurement, is analyzed in Appendix II in considerable mathematical detail. The major part of such an analysis centers around the investigation of the existence, uniqueness, and stability of limit cycles (hunting in the steady state).

If the input is of a more complex nature, the analysis in the phase plane becomes more cumbersome, but not altogether impossible. On the other hand, if the system cannot be described by a single degree of freedom, then the motion no longer can be represented in a plane. If, then, the analogy to the one-degree-of-freedom case is to be extended, the motion must be represented in spaces of higher dimensions. Accordingly, the geometric picture breaks down altogether and the analysis becomes far more complex.

Minimum Signals from Null Devices

In many types of feed-back control systems the primary control action is to balance two signals in a null. A servomechanism used to indicate the out-of-balance of a resistance strain gage by comparing the bridge unbalance with a voltage-divider position is a good example. Here the signal will be a remote positioning servomechanism with synchro data transmission. Here the error measuring device is fundamentally a variable ratio transformer.

In practice it is well known that none of these voltage-sensing null systems are ideal. Their departure from the ideal is the most important aspect in their consideration. As the regulating system moves toward balance, let us consider the approach of the error-sensing device to zero signal.

1. It may be very possible for some unwanted source to produce an effect on the true error signal, in addition to the motion of the regulated quantity. The stepwise characteristics of a potentiometer produce a step effect which is of this sort. The winding inaccuracies in synchros produce an effect which may be thought of in this light.
2. There may be, in a-c systems, a quadrature voltage. Although small compared to a large error signal, it may predominate when balance is near.
3. There may be harmonic voltages in a-c systems.
4. There may be "pick-up" resulting in a voltage of indefinite relation to the true error signal.
5. There may be a purely random signal caused by thermal agitation in resistive elements or an equivalent phenomenon. An attempt has been made to represent these elements in a circuit as a part of Figure 3.

The designer of regulating systems can do something about most of the items of Figure 3. If the positioning inaccuracies are troublesome, an attempt is made to make unit motion of the regulated quantity cause more motion of the null indicating system. High-speed synchro systems are examples of this technique. If the quadrature voltage is high, a phase-sensitive rectifier not sensitive to quadrature signals may be used to interpret the signals,[10] or, alternatively, a bucking voltage can be inserted. If the harmonics are high, the iron structure of transformer instruments may be saturating. If this cannot be avoided then null networks of the bridged-T type may be cascaded with the error signal to eliminate the harmonics. An example of this latter technique is found in some conical-scanning automatic-tracking radar sets. When random signals play an important role, the basic requirements of the system are analyzed very carefully, and its performance is optimized by filter circuits which cut out all the overcapacity in the system frequency response.

All this is to say that the nonideal signals are not wanted. It might well be asked what would result from their transmission. To study this it will be presumed that a small amount of each is present and cannot be eliminated. The results of such consideration are shown in Table II.

In presenting the information in Table II, the authors are quoting from a limited experience. Free discussion is encouraged among the readers to improve the accuracy of the statements made.

Table II. Consideration of Inaccuracies of Null Instruments, with Quiescent Regulating Input

Source of Inaccuracy in Null Instrument	Effect on Regulator (Input Quiescent)	Remedy
Inaccuracy of positioning instrument	1-to-1 error in positioning regulated quantity	Increase speed of data transmission
Harmonic source	Causes partial saturation in error channel, thus limiting gain allowable. Causes no error in positioning regulated quantity	Selective filters in cascade with instrument
Quadrature source	Causes partial saturation in error channel, thus limiting gain allowable. Causes no error in positioning regulated quantity	Selective phase sensitive detector Buckling voltage
Pick-up	Causes some error in output, some saturation of error channel, sometimes unpredictable jumps and jitters in output	Shielding and grounding. (System is often sensitive to which side of a transformer coil is grounded.) Eliminate excessive adding of signals with high impedance source Reduce source impedance
Random signals with spectral density $G_N(f)$	Random motion of output result	Optimum design of filter Reduce impedance of instrument Redesign instrument to minimize cause of random signal

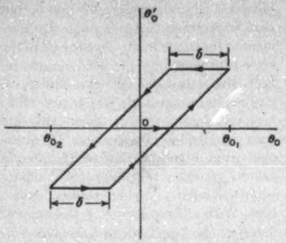

Figure 4. Relationship between angular position of two gears between which backlash exists

Examination of Table II will show that the major difficulty in a null-balancing system is to minimize the unwanted parts of the signal, so that high gain can be used most effectively. The usual mathematics of regulating systems do not include the fact that saturation can occur in the system (at different parts depending on the particular components). Hurewicz and Nichols[8,9] have described analytical means of studying the effect of saturation by means of the phase plane. In these studies the desired quantity, θ_i, was caused to suddenly move at a constant rate. Resulting trajectories for the system were plotted in a plane whose abscissa is the regulated quantity and whose ordinate is the rate of change of the regulated quantity. Tendencies toward instability which may result from saturation thus could be studied. In high performance regulating systems, however, the partial saturation caused by unwanted signals should be kept to a few per cent for reasons other than instability. But when the range of proportional signal is restricted, such an analysis is important to determine the recovery from large disturbances.

Description of System in Which Effect of Backlash Is Described

For the purpose of investigating the effects of backlash, a simple feed-back control system is assumed as shown in Figure 1. The backlash occurs in the instrument whose function it is to sense the output of the control system and feed-back to the comparator a signal proportional to this output. The comparator is assumed ideal here in its function of sending to the controller the difference between input signal and output of the output-sensing device. The input to the system is a shaft rotation, designated θ_i in Figure 1. The output is a shaft rotation, θ_o. The output-sensing device, whose output is θ_o', is assumed ideal in all respects except for the presence of backlash. The backlash is of such character as to result in a relationship between θ_o and θ_o' described by the graph of Figure 4. This figure shows values assumed by θ_o' as the output shaft moves with finite velocity from a position $\theta_o=0$ to a position where θ_o has some positive value, θ_{o1}, greater than 1/2 the backlash angle; then reverses direction of rotation so that θ_o decreases through zero to some negative value θ_{o2}, greater than 1/2 the backlash angle; then reverses again, returning once more to θ_{o1}. δ is the total backlash angle or dead zone, and it is assumed that the coupled components between which backlash exists are initially at the midpoint of the dead zone.

The type of backlash described in Figure 4 is somewhat idealized. If we suppose that the backlash exists between the teeth of a pair of gears, the characteristic shown in Figure 4 implies that there is no elasticity, slippage, or other condition present that would impair the perfect transmission of motion when the gears are in contact with each other, and, on the other hand, that the driven gear has no motion except such as is imparted to it by the driving gear, and that only while there is contact. It should be noted here that a graph similar to that of Figure 4 was used by Schlink,[4] who discussed backlash as an instrument inaccuracy in 1918.

The comparator subtracts θ_o' from θ_i to obtain the error, ϵ, which is fed to the controller in a form which it can accept. The controller operates on the error to produce a signal capable of driving the servomotor. The effects of backlash are described for five different types of controllers. Designating the output of the controller as ϵ', the five controllers are

$$\frac{\epsilon'}{\epsilon}=K \tag{1}$$

$$\frac{\epsilon'}{\epsilon}=K(1+T_Dp) \tag{2}$$

$$\frac{\epsilon'}{\epsilon}=K\left(1+\frac{1}{T_ip}\right) \tag{3}$$

$$\frac{\epsilon'}{\epsilon}=K\left(1+T_Dp+\frac{1}{T_ip}\right) \tag{4}$$

$$\epsilon'=K\left(1+\frac{1}{T_ip}\right)\epsilon+KT_\theta p\theta_0 \tag{5}$$

where

K = a constant
T_D = a time constant
T_i = a time constant

Linear operation of both motor and controller is assumed. The total load on the output shaft of the servomotor consists of inertia and viscous friction.

A mathematical analysis of the effect of backlash for the controllers of equations 1 and 2 is described in Appendix II.

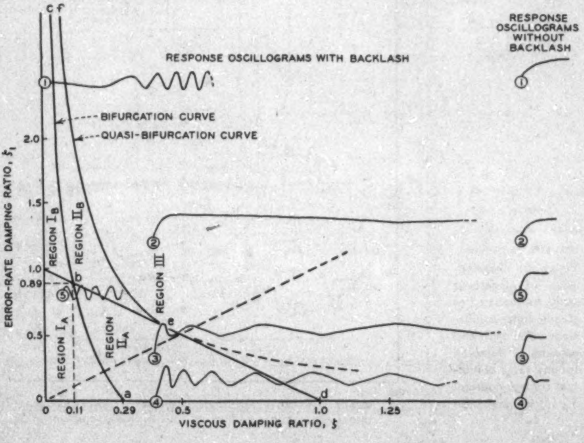

Figure 5. The zeta plane of a single-degree-of-freedom system having backlash in measurement of the output quantity

Region I. Continuous oscillations

Region III. Exponential decay

This was used to amplify to and corroborate experimental studies made on an electrical analog of the system described above. The analog is described in Appendix I and follows the techniques described by Ragazzini, Randall, and Russell.[11]

Behavior of Selected Systems in Presence of Backlash

The behavior of feed-back control systems in the presence of backlash is found to be critically dependent upon the type of control action used. The behavior of the single-degree-of-freedom system employing error-rate and/or viscous damping is described in terms of the proportions of these two types of damping. The behavior of the same system with the addition of integral control (see equations 3, 4, and 5) is described in terms of magnitude and frequency of the ever-present oscillations.

Figure 5 summarizes the analytical and experimental data for a single-degree-of-freedom system with backlash. This figure is described as a zeta plane. The abscissa is the damping ratio if only viscous damping were present; the ordinate is defined as the damping ratio if only error-rate damping were present. The sum of these two damping ratios is the total damping ratio of the system. For viscous damping ratios of the order of 0.3 or greater, the response of the computer to a disturbance depends on the total damping and on the relative amount of error-rate damping. If the total damping is less than critical, the response of the system is a transient oscillation of increasing period. The amplitude of the first cycle of the oscillation is greater than it would be in the absence of backlash, by an amount which may be as great as the backlash angle; successive overshoots decrease in amplitude until the output shaft hunts back and forth through an angle equal to that of the dead zone. The period of the oscillation increases, apparently indefinitely. It takes a longer time and a greater number of cycles of oscillation, for the system to settle down to the quasi-steady state of hunting within the limits of the dead zone, than are required by the system without backlash to attain a steady-state condition. If the total damping is greater than critical and the viscous damping ratio is about 0.5 or greater, the transient response of the system will be an exponential asymptotic to one edge of the backlash zone. If the viscous damping ratio is between 0.3 and 0.5, either the exponential response or the quasi-hunting with increasing period may occur depending on the amount of error-rate damping.

For viscous damping ratios below 0.3, the system may exhibit any one of three modes of behavior. It may oscillate continuously in the steady-state with an amplitude which is in general greater than the backlash angle and an inverse function of the total damping; or it may exhibit the quasi-hunting response with increasing period; or it may respond in the exponential manner. Which of these three modes of behavior takes place will depend on the amount of viscous damping and the total damping in the system.

The addition of an integral term in the control function, equations 3, 4, and 5, renders the system at all times oscillatory in the presence of backlash. The amplitude and frequency of the steady-state oscillation are functions of the total damping, the relative amounts of viscous, error-rate, and tachometric damping, and to a lesser extent, of the magnitude of the integral term in the control function.

Figure 6 illustrates this relationship for a single value of integral control constant, $T_i = 1/8$ and a single value of $\omega_n = 24$. The small figures placed at points along each of the curves of Figure 6 indicate the kind of oscillogram that is obtained of the motion of the output shaft in response to a step-angle displacement of the input shaft. In the case of the error-rate damping, the oscillograms reflect the saturation of the derivative channel in response to a step input. This however, does not affect the steady-state data described by the curves. It can be seen from Figure 6 that, with integral control, the effect of tachometric damping is quite similar to that of viscous damping. With either viscous or tachometric damping the amplitude and frequency of the steady-state oscillation can be many times the magnitude of the backlash. It would seem, then, that the design requirement is for much more than usual damping with integral control in the presence of backlash. In the case of error-rate damping, the behavior of the system under conditions of low total damping approaches that of the system under comparable conditions of viscous or tachometric damping. However, for large amounts of error-rate damping the system exhibits two modes of behavior, depending on the amount of viscous damping present. The experienced servomechanism engineer will recognize the high-frequency chatter so often observed with error-rate damping. It is interesting to note that this can occur for zero coulomb friction loads.

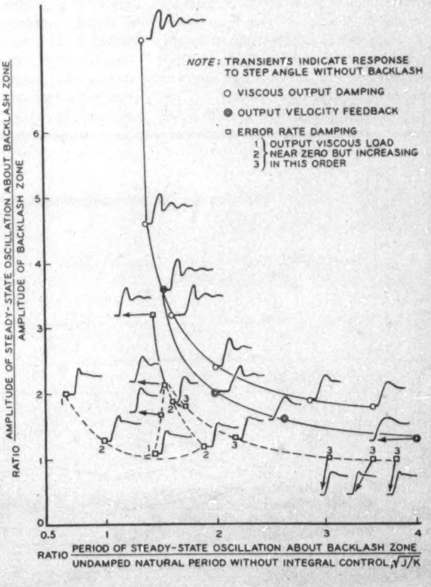

Figure 6. Dependence of magnitude and frequency of steady-state oscillations upon type and amount of damping for one value of integral control constant $T_i = 1/8$ and for $\omega_n = 24$

Summary Discussion of the Effects of Backlash in Feed-Back Control Systems

It would appear from analyzer data and analysis of Appendix II that it may be practical to devise a qualitative picture of steady-state behavior of feed-back control mechanisms in the presence of backlash. The backlash zone may be considered as bounded on either side by barriers having special resilient or energy-giving properties dependent upon the type of control. Pure gain seems analogous to a resilient barrier with the stiffness proportional to gain. Here the penetration of the barrier by the mechanism is a function of the energy at the time of entry, and the energy gained is a function of the time and penetration into the barrier region. With integral control the energy flow aiding the oscillation continues even after the mass has been repulsed from the barrier. Here the rate of energy flow to the mechanism during its next sweep across the dead space is determined by the penetration and the time in the barrier. The effects of various kinds of damping can be seen as primarily determining the speed of the sweep across the backlash zone and thus the energy at the time of entry into the barrier region. The action of error-rate damping is different from the others in the barrier region in that additional repulsive force is developed, giving an artificial stiffness to the barrier. It already has been shown how this effect can become dominant, giving rise to a high-frequency chatter so often associated with error-rate damping in the presence of backlash. Although the authors have not yet studied the effects of coulomb friction and stiction, it would appear from the foregoing reasoning that a difference between coulomb friction and stiction would aggravate the tendency toward large oscillations.

The general effects of backlash of the type studied are to introduce an inaccuracy of magnitude greater than the actual backlash and to destabilize the system. Under some conditions a disturbance in the system may lead to complete uncontrolled instability, whereas if the backlash were absent, the effects of the disturbance would have damped out. Where the effects of a disturbance in the system with backlash do damp out, it takes a longer time for them to be reduced to near-steady-state conditions. This indicates that much high speed of response performance may be lost due to the presence of backlash. Under other conditions of parameter adjustment than the conditions of complete instability or damping out of transients, there can be continuous oscillations of magnitude several times the backlash.

The assumption made in this study—that the backlash was confined to one point in the system—was, of course, an arbitrary one. It was dictated partly by the main topic of this paper, which is a discussion of instrument inaccuracies, and partly by the necessity of simplifying the problem. It would be of considerable value to study further the effects of backlash at other points, or combinations of points, in the system. In addition, it is desirable to extend the study to more complicated systems, to study the effects of coulomb friction and stiction, and possibly, to apply statistical methods to the case where there are numerous sources of backlash.

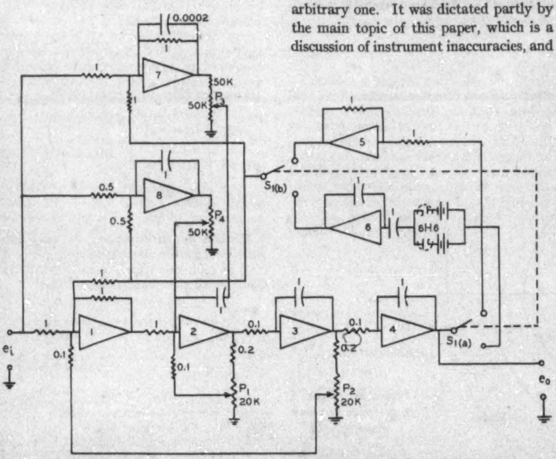

Figure 7. Electrical analog based on d-c amplifier technique as used to study effects of backlash

Unless otherwise noted resistances are given in megohms, and capacitances are given in microfarads

Appendix I. The Analog Computer

Analog studies and mathematical analysis constitute a powerful and fruitful combination in the investigation of nonlinear phenomena. Besides serving as a check, each method produces results which give meaning and direction to the investigations carried out by the other method. Thus, the appearance of a peculiar mode of behavior as observed in the analog study suggests to the mathematician engaged in a phase-plane analysis that he should look for the existence of a limit cycle of which he might not otherwise have been aware; the mathematician's verifying the existence of this limit cycle is assurance that the observed mode of behavior was not due to a concealed imperfection in the analog representation of the system under study. On the other hand, the mathematician may predict from his analysis that the mode of behavior of the system will change for a certain combination of parameters, a fact which the analog investigator might not have discovered except by accident or the application of an infinite amount of patience in setting into the analog all possible combinations of parameters. The manner in which these two methods complement each other is especially felicitous in the investigation of nonlinear systems, since changes in mode, athough expected, may be very difficult to predict, and extrapolation from one set of system conditions to another can seldom be made with assurance.

The electrical analog used in this study is shown in Figure 7. Amplifier *6*, together with its input and feed-back capacitors, the dual diode, and the batteries, constitute the backlash analog. By means of switch S_1 backlash can be inserted into or removed from the analog. The undamped natural frequency of the system is set by means of potentiometer P_1, and the viscous damping by means of potentiometer P_3. Potentiometer P_2 sets the error-rate damping coefficient, T_d, and potentiometer P_4 sets the integral-control coefficient, T_i. The small capacitor placed between the output and input of amplifier *7* was inserted to stabilize one of the loops in the analog. It will be recognized, of course, that the analog is inexact for a suddenly applied displacement of the servomechanism input shaft, since such a disturbance results in an infinite pulse in the derivative of the error, a condition which cannot be realized by any physical analog. In the study of the single-degree-of-freedom system in which a derivative term was inserted in the control function, the transient response of the system was studied by simulating the sudden application of a constant-load torque applied to the output shaft. In all other cases, the system was disturbed by application of a step angle to the input shaft, in some cases, then, reflecting saturation of the derivative circuits.

To obtain data for the tachometric case an additional loop was added to the analog of Figure 7. The coupling between output shafts and tachometer is assumed free of backlash, since this is usually the case in practice. A brief examination will show that, as far as the analog is concerned, tachometric and viscous damping are identical for the single-degree-of-freedom system but not for the integral-control system. The component of output rate is integrated as well as directly transmitted when there is integral control.

Appendix II. Phase-Plane Analysis of Single-Degree-of-Freedom Feed-Back Control System with Backlash in Measurement of Controlled Quantity (Constant Displacement Input)

Symbols

J = mass moment of inertia
C = coefficient of viscous damping
k = spring constant
$C_1 = kT_D$ = effective derivative control damping
t = time
θ_i = input
θ_0 = output
θ_0' = backlash output
Other symbols are defined as they occur in the text.

It is assumed that backlash gears are free and have no inertia and an arbitrarily small amount of damping (say, dry friction).

General

From Figure 1, the differential equation of the system is

$$J\frac{d^2\theta_o}{dt^2}+C\frac{d\theta_o}{dt}=k\epsilon+C_1\frac{d\epsilon}{dt} \tag{1}$$

where $\epsilon=\theta_i-\theta_0'$ is the "error," while for a constant displacement input $\theta_i(t)=\theta_i^{(0)}=$ constant. Equation 1 can-be written

$$\frac{d^2\theta_o}{d\tau^2}+2\left(\zeta\frac{d\theta_o}{d\tau}+\zeta_1\frac{d\theta_o'}{d\tau}\right)+\theta_o'=\theta_i^{(0)} \tag{2}$$

where

$$\left.\begin{aligned}
&\tau=\text{nondimensional time}=\omega_n t\\
&\omega_n=\sqrt{\frac{k}{J}}\\
&\zeta=\frac{C}{C_c}=\frac{1}{2}\frac{C\omega_n}{k}\\
&\zeta_1=\frac{C_1}{C_c}=\frac{1}{2}T_D\omega_n\\
&C_c=2J\omega_n
\end{aligned}\right\} \tag{3}$$

As will appear presently, the introduction of ζ_1 and, in particular, the introduction of a "damping" plane, (ζ, ζ_1), turns out to be of real advantage in the analysis. In general

$$\theta_o'=a+b\theta_o$$

Let the backlash angular gap be δ; we may assume, without loss of generality, that the output gear starts from a position just midway between the teeth of the backlash gear, so that when the two gears are in contact, θ_o' either lags or leads θ_o by an angle of amount $(1/2)\delta$. This convention is introduced merely for purposes of symmetry. If the relative position of the gears at starting is different, that means merely a shift of the $d\theta_o/dt$ axis in the phase plane. All results derived in following paragraphs are invariant with respect to any co-ordinate transformation. We have the following:

When the gears are in contact

$$b=1 \tag{4}$$

and by convention

$$a=-\frac{1}{2}\delta \text{ for } \frac{d\theta_o}{dt}\geq 0$$

$$=+\frac{1}{2}\delta \text{ for } \frac{d\theta_o}{dt}\leq 0$$

When the gears are unmeshed

$$b=0$$

and by convention

$$a=\theta_o^{(0)}+\frac{1}{2}\delta \text{ for } \frac{d\theta_o}{dt}\geq 0$$

$$=\theta_o^{(0)}-\frac{1}{2}\delta \text{ for } \frac{d\theta_o}{dt}\leq 0$$

where

$$\theta_o^{(0)}=\theta_o \text{ at } \frac{d\theta_o}{dt}=0 \tag{5}$$

Equation 5 is true in general, except for a part of the very first cycle.

Finally, let $\zeta_2=\zeta+\zeta_1$ = total effective (nondimensional) damping. As in the ordinary case, the trajectories in the phase-plane $(\theta_o, d\theta_o/dt)$ assume different forms according as $\zeta_2 \lessgtr 1$, that is, according as the system is effectively under- or overdamped.

$\zeta_2 \leq 1$, Underdamped Systems

Gears Meshed. Let

$$\xi=\frac{\theta_o}{\theta_i^{(0)}}-1 \quad \alpha=\frac{1}{2}\frac{\delta}{\theta_i^{(0)}} \quad W=\frac{d\xi}{d\tau} \tag{6}$$

Then the differential equation is

$$\frac{d^2\xi}{d\tau^2}+2\zeta_2\frac{d\xi}{d\tau}+\xi=\pm\alpha\begin{pmatrix}+\alpha \text{ for } W\geq 0\\ -\alpha \text{ for } W\leq 0\end{pmatrix}$$

Let

$$\xi=\xi(0) \text{ at } W=\frac{d\xi}{d\tau}=0$$

Without loss of generality, we may also write $\tau=0$ for the above conditions. For if $\tau\neq 0$ at $\xi(0)$, this merely entails a shift in time. With these conditions, we find

$$\frac{\xi\mp\alpha}{\xi(0)\mp\alpha}=\epsilon^{-\zeta_2\tau}\left(\cos\sqrt{1-\zeta_2^2}\,\tau+\frac{\zeta_2}{\sqrt{1-\zeta_2^2}}\times \sin\sqrt{1-\zeta_2^2}\,\tau\right)$$

$$\frac{W}{\xi(0)\mp\alpha}=-\frac{\epsilon^{-\zeta_2\tau}}{\sqrt{1-\zeta_2^2}}\sin\sqrt{1-\zeta_2^2}\,\tau$$

$$\tau=\frac{1}{\sqrt{1-\zeta_2^2}}\tan^{-1}\left(\frac{-\sqrt{1-\zeta_2^2}\,W}{\xi\mp\alpha+\zeta_2 W}\right)= -\frac{1}{2\zeta_2}\log_\epsilon\left[\frac{(\xi\mp\alpha)^2+2\zeta_2(\xi\mp\alpha)W+W^2}{(\xi(0)\mp\alpha)^2}\right] \tag{7}$$

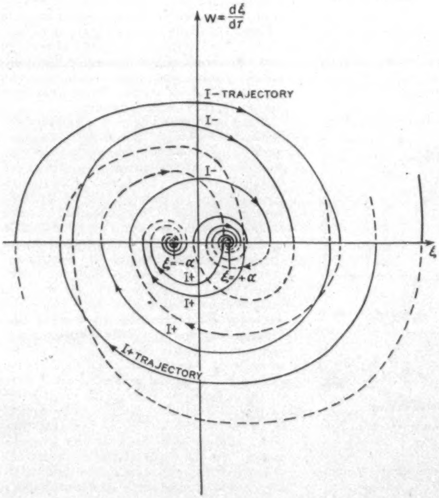

Figure 8. Type I trajectories in phase plane ($\zeta_2<1$)

Arrows indicate increasing time. Singular (focal) points at $\xi=\pm\alpha$; $W=0$. Curves are not drawn to scale

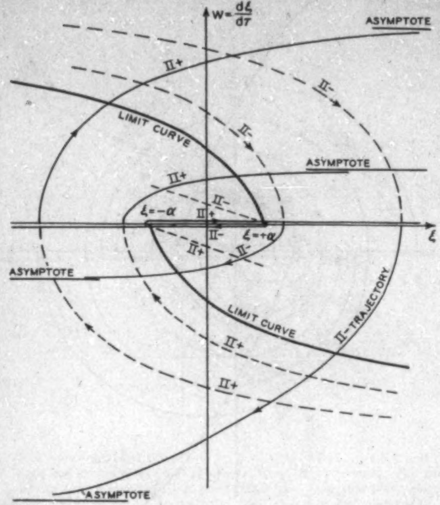

Figure 9. Type II trajectories and limit curves in phase plane ($\zeta_2<1$)

Arrows indicate increasing time. Singular (focal) points at $\xi=\pm\alpha$; $W=0$. Curves are not drawn to scale

Equation 7 is the equation for the trajectories in the phase plane. These trajectories are general spirals and are shown in Figure 8. These curves are marked I_+, I_- according as $+\alpha$ or $-\alpha$ is written in the equations. In accordance with our convention time increases along the trajectories in a clockwise direction, as indicated by the arrows.

The I_+ trajectories tend to $\xi=-\alpha$, $W=0$ as $\tau\to+\infty$. As will be seen soon, only the lower parts of trajectories I_+ and the upper parts of trajectories I_- will come into consideration. Hence the other parts have been drawn with dotted lines in Figure 8. On the lower part of any I_+ trajectory (except the "last" one, that is, a point) we have

$$0\geq\tau\geq-\infty\,;\,0\geq\tan^{-1}\left(\frac{-\sqrt{1-\zeta_2^2}W}{\xi+\alpha+\zeta_2W}\right)\geq-\pi$$

The zero value of the arc tangent is to be taken at $\xi=\xi(0)<-\alpha$; $W=0$. The minima of the lower part of I_+ occur at $\xi+\alpha=-2\zeta_2W>0$, that is, on the other side of $\xi=-\alpha$. Analogous results hold, of course, for the I_- curves.

Gears Unmeshed. The differential equation is

$$\frac{d^2\xi}{d\tau^2}+2\zeta\frac{d\xi}{d\tau}=-(\xi(0)\pm\alpha)\begin{pmatrix}+\alpha \text{ for } W\geq0\\ -\alpha \text{ for } W\leq0\end{pmatrix}$$

From which

$$\tau=-\frac{W+2\zeta[\xi-\xi(0)]}{\xi(0)\pm\alpha}$$

and the trajectories in the phase plane are given by

$$W+2\zeta[\xi-\xi(0)]=\frac{\xi(0)\pm\alpha}{2\zeta}\times \log_e\left[1+2\zeta\frac{W}{\xi(0)\pm\alpha}\right] \qquad (8)$$

For $+\alpha$ only the upper parts and for $-\alpha$ only the lower parts of the curves are of interest.

TYPE II_+ CURVES ($+\alpha$)

$\xi(0)+\alpha\leq0$; τ increases with W; W(at $\tau\to\infty)\to-(\xi(0)+\alpha)/2\zeta$ that is, $W=-(\xi(0)+\alpha)/2\zeta\geq0$ is horizontal asymptote; $\xi\geq\xi(0)$. Analogous results hold for the II_- curves; these curves are shown in Figure 9.

LIMIT CURVES

Consider a typical curve of, say, Type II_-; $W\leq0$; this curve which passes through $\xi=\xi(0)$, $W=0$, $\tau=0$ will not apply after ξ has been decreased by 2α, for then the gears which were unmeshed at $\xi=\xi(0)$ will mesh again, and the motion will resume on a trajectory of Type I_+. The locus of the points where the motion passes from trajectories II_- to trajectories I_+ will be designated as a limit curve. It can be easily verified that its equation is

$$W-\frac{\xi+\alpha}{2\zeta}\log_e\left(1+2\zeta\frac{W}{\xi+\alpha}\right)=4\zeta\alpha$$

$$W\leq0 \quad \xi+\alpha\geq0 \quad 0\leq-\frac{W}{\xi+\alpha}\leq\frac{1}{2\zeta} \qquad (9)$$

It can be verified that

$$\lim_{\substack{\xi+\alpha\to0\\ -W\to0}}\left(-\frac{W}{\xi+\alpha}\right)\to\frac{1}{2\zeta}$$

$$\lim_{\substack{\xi+\alpha\to\infty\\ -W\to\infty}}\left(-\frac{W}{\xi+\alpha}\right)\to0$$

$$\lim_{\substack{\xi+\alpha\to0\\ -W\to0}}\left(-\frac{dW}{d\xi}\right)\to\frac{1}{2\zeta}$$

$$\lim_{\substack{\xi+\alpha\to\infty\\ -W\to\infty}}\left(-\frac{dW}{d\xi}\right)\to0$$

and finally that both $-W/(\xi+\alpha)$ and $(-dW/d\xi)$ decrease monotonically as $\xi+\alpha$ increases from 0 to ∞. Analogous results hold for the upper limit curve which starts at $\xi=\alpha$ and proceeds to the left with $W\geq0$. These limit curves are shown in Figure 9.

LIMIT POINTS AND LIMIT CYCLE

Consider Figure 10. The upper parts of the I_- and II_+ trajectories, the lower parts of the I_+ and II_- trajectories, and the upper and lower limit curves are shown.

Now suppose that at a certain instant the motion of the system is characterized by a point on a I_- trajectory, say between points *2'* and *1*. Then, at $W=0$, $\xi=\xi(0)$, the motion will leave the I_- trajectory and will proceed on a II_- trajectory up to point *2* on the limit curve. Thence the motion will proceed on a I_+ trajectory up to point *1'* at $W=0$, $\xi=-\xi'(0)$. Three alternatives are possible

$$\left|\xi'(0)\right|\substack{<\\=\\>}\left|\xi(0)\right|$$

If the equality sign holds, then, because of symmetry, the motion will proceed from *1'* to *2'* on trajectory II_+ and, finally, from *2'*, along trajectory I_-, back to point *1*. In this case a limit cycle exists, that is, there exists the possibility of hunting in the steady state with an amplitude greater than the reduced backlash gap 2α.

It is now necessary to investigate:

1. **What is the criterion for the existence of such a limit cycle?**
2. **Can there exist more than one such limit cycle?**
3. **Is such a limit cycle stable? That is, will the motion tend towards the limit cycle or away from it?**
4. **If the limit cycle is stable, is it stable only relative to a certain region (or regions) in the phase plane, or stable relative to all trajectories in the phase plane? If the first alternative is true, then only transients that originate in a certain defined region in the phase plane tend to hunting, while the others do not. In the second case, however, all transients, no matter where they might originate in the phase plane, must end up in hunting in the steady state.**

The following can be proved:

1. Let x satisfy the equation

$$(1+2\zeta_2x+x^2)\,\exp\left[\frac{2\zeta_2}{\sqrt{1-\zeta_2^2}}\tan^{-1}\left(\frac{-\sqrt{1-\zeta_2^2}\,x}{1+\zeta_2x}\right)\right]=1$$

$$0<-x<\infty \quad 0<\zeta_2<1 \quad x=\frac{W}{\xi+\alpha}\text{(for lower limit curve)} \qquad (10)$$

Then, if $-x<1/2\zeta$, a limit cycle exists. Substituting $-x=1/2\zeta$ into equation 10 and remembering that $\zeta_2=\zeta+\zeta_1$, there results an equation which represents a curve in the damping (ζ, ζ_1) plane. This equation is valid, of course, only in the region $\zeta_2=\zeta+\zeta_1\leq1$. This curve is shown in Figure 5, passing through points *a* and *b*, and, for reasons that will become clear later, marked "Bifurcation curve."

2. There always exists one, but only one, value of x which satisfies equation 10. From this, it follows that there cannot exist more than one limit cycle.

3. If a limit cycle exists, then if a point crosses the $+\xi$ axis at $\xi_1>\xi(0)$ (see Figure

10), it will cross the $-\xi$ axis at $\xi=-\xi_3$ such that $\xi(0)<\xi_3<\xi_1$ and, conversely, if $\xi_1<\xi(0)$ then $\xi_1<\xi_3<\xi(0)$. Hence trajectories in the phase plane approach the limit cycle monotonically either from within or from without. That is, the hunting cycle is approached either with constantly increasing amplitude and decreasing period or in the opposite manner.

4. This is true for all trajectories in the phase plane. Hence the limit cycle is stable in the large, that is, with respect to the entire phase plane, and all transients must end up in hunting in the steady state, with a fixed period and amplitude greater than the reduced backlash gap $2\alpha=\delta/\theta_i^{(0)}$.

Finally, if $-x>1/2\zeta$, the limit points *2* and *2'*, Figure 10, coalesce into the singular points $\xi=\mp\alpha$ respectively, while the limit cycle degenerates into the ξ axis strip

$$-\alpha\leq\xi\leq\alpha \quad W=0$$

This degenerate limit cycle is a limit case of hunting in the steady state with an amplitude equal to the reduced backlash amplitude 2α, and with zero frequency. All trajectories approach this degenerate limit cycle from without with decreasing amplitude tending to 2α and with ever-increasing period. The designation quasi-hunting seems to be appropriate.

Thus the curve given by equation 10 with $-x=1/2\zeta$ and shown in Figure 5 (bifurcation curve through points *a* and *b*) divides the region $\zeta+\zeta_1=1$, $(\zeta_2>0, \zeta_1>0)$ into two regions marked I_A and II_A. In region I_A all transients end up in hunting in the steady state, while in region II_A all transients end up in what was defined above as quasi-hunting. This holds true so long as there is any finite amount of backlash. The backlash gap enters, of course, in the quantitative values of amplitude, ratio of successively increasing periods in the case of quasi-hunting, and so forth.

Since detailed proofs of the above statements would unduly enlarge this paper, they have been omitted.

$\zeta_2=\zeta+\zeta_1>1$, Effectively Overdamped System

Gears in Contact. The differential equation is

$$\frac{d^2\xi}{d\tau^2}+2\zeta_2\frac{d\xi}{d\tau}+\xi=\pm\alpha$$

where, as already defined

$$\xi=\frac{\theta_0-\theta_i^{(0)}}{\theta_i^{(0)}} \quad \alpha=\frac{1}{2}\frac{\delta}{\theta_i^{(0)}}$$

Again, if $\xi=\xi(0)$ at $W=0$, $\tau=0$, then

$$\frac{\xi\mp\alpha}{\xi(0)\mp\alpha}=\epsilon^{-\zeta_2\tau}\left(\cosh\sqrt{\zeta_2^2-1}\,\tau+\frac{\zeta_2}{\sqrt{\zeta_2^2-1}}\sinh\sqrt{\zeta_2^2-1}\,\tau\right)$$

$$\frac{W}{\xi(0)\mp\alpha}=-\frac{1}{\sqrt{\zeta_2^2-1}}\epsilon^{-\zeta_2\tau}\sinh\sqrt{\zeta_2^2-1}\,\tau \tag{11}$$

$$\tau=-\frac{1}{2\zeta_2}\log_\epsilon\left[\frac{(\xi\mp\alpha)^2+2\zeta_2(\xi\mp\alpha)W+W^2}{(\xi(0)\mp\alpha)^2}\right] \tag{12}$$

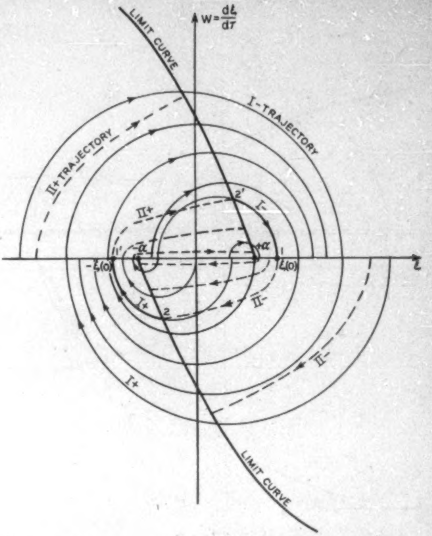

Figure 10. Types I and II trajectories, limit curves, and limit cycle in phase plane ($\zeta_2<1$) limit points: 2 and 2', limit cycle: 1-2-1'-2'-1

Arrows indicate increasing time. Singular (focal) points at $\xi=\pm\alpha$; $W=0$. Curves are not drawn to scale

After eliminating τ we get the equation of the trajectories in the phase plane

$$a_1\log\left(\frac{\frac{W}{a_1}+\xi\pm\alpha}{\xi(0)\pm\alpha}\right)=a_2\log\left(\frac{\frac{W}{a_2}+\xi\pm\alpha}{\xi(0)\pm\alpha}\right) \tag{13}$$

where

$$a_1=\zeta_2+\sqrt{\zeta_2^2-1}\geq1$$

$$a_2=\zeta_2-\sqrt{\zeta_2^2-1}=\frac{1}{a_1}$$

$$0\leq a_2\leq1$$

These curves are shown in Figure 11; curves III_{A+} for $+\alpha$ and curves III_{A-} for $-\alpha$; at $\tau\rightarrow-\infty$ these curves tend to become parallel to the line $W=-a_1(\xi\pm\alpha)$, and at $\tau\rightarrow+\infty$ they become asymptotic to the line $W=-a_2(\xi\pm\alpha)$. These asymptotes will be designated accordingly as asymptotes $1_\pm$, $2_\pm$. It will be seen that the curves so far discussed do not enter the space between the two pairs of asymptotes, that is, between asymptotes 1_+ and 2_+ and between 1_- and 2_-. To determine the equations of the trajectories in these regions, we proceed as follows:

We may consider $\alpha=0$ since this merely means a shift in the W axis. Then the differential equation is

$$\frac{d^2\xi}{d\tau^2}+2\zeta_2\frac{d\xi}{d\tau}+\xi=0$$

Now suppose that the initial conditions are

$$\text{at } \tau=0 \quad \xi=x \quad W=\frac{d\xi}{d\tau}=-kx \quad k>0$$

Then we find

$$\xi=\frac{x}{2\sqrt{\zeta_2^2-1}}\epsilon^{-\zeta_2\tau}[(a_1-k)\epsilon^{\sqrt{\zeta_2^2-1}\,\tau}-(a_2-k)\epsilon^{-\sqrt{\zeta_2^2-1}\,\tau}]$$

$$W=-\frac{x}{2\sqrt{\zeta_2^2-1}}\left[\frac{a_1-k}{a_1}\epsilon^{\sqrt{\zeta_2^2-1}\,\tau}-\frac{a_2-k}{a_2}\epsilon^{-\sqrt{\zeta_2^2-1}\,\tau}\right] \tag{14}$$

and

$$-\frac{W}{\xi}=a_1\left[1-\frac{1-\frac{a_2}{a_1}}{1+\frac{k-a_2}{a_1-k}\epsilon^{-(a_1-a_2)\tau}}\right]$$

$$=a_2\left[1+\frac{\frac{a_1}{a_2}-1}{1+\frac{a_1-k}{k-a_2}\epsilon^{(a_1-a_2)\tau}}\right] \tag{15}$$

Since

$$a_1\geq1, \quad a_2\geq0, \quad 0\leq\frac{a_2}{a_1}\leq1, \quad \epsilon^{a_1\tau}\geq0, \quad \epsilon^{a_2\tau}\geq0$$

It can be seen from the foregoing equations that if

$$a_2\leq k\leq a_1$$

then

$$a_2\leq\left(-\frac{W}{\xi}\right)\leq a_1$$

That is, the trajectories given by equation 14 never pass out of the regions between the asymptotes once they have started in those regions. Furthermore, it is easy to verify

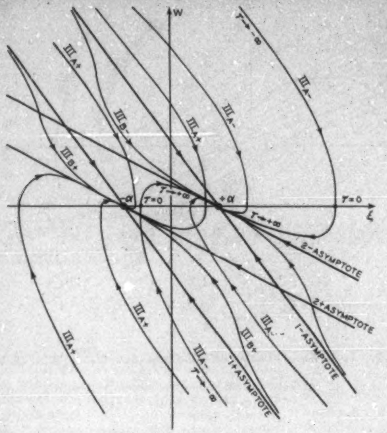

Figure 11. Type III trajectories and asymptotes in phase plane $(\zeta_2>1)$

Arrows indicate increasing time. Singular (nodal) points at $\xi=\pm\alpha$, $W=0$. Curves are not drawn to scale

from equations 15 that as $\tau\to-\infty$, $(-W/\xi)\to a_1$, and as $\tau\to+\infty$, $(-W/\xi)\to a_2$. These curves are marked III_{B+} and III_{B-} in Figure 11.

It is seen from equations 15 that, except for the asymptotes themselves which are also trajectories ($k=a_1$ or $k=a_2$), these trajectories are not straight lines. In pages 19 and 76 of reference 13, these curves are shown as straight lines, apparently by an oversight.

Gears Unmeshed. Since ξ_1 does not enter into the differential equation, the type II_+ and II_- trajectories and the limit curves that have been discussed already in the underdamped case apply without any change in this case too.

Limit Points and Limit Cycles

In contradistinction to the underdamped case, the situation is now different according as $a_1 \gtrless 1/2\zeta$.

$a_1>1/2\zeta$ means that the slope of the limiting curve (upper or lower) at $W=0$ is less than the slope of the 1_+ or 1_- asymptote. This case is shown in Figure 12; a study of this figure shows that in this case all transients damp out exponentially, with no, or at most one, overshoot, except possibly an additional overshoot due to the initial disturbance. All trajectories tend to either of the two singular (nodal) points $\xi=\pm\alpha$, $W=0$, either from within or from without the region $-\alpha\leq\xi\leq\alpha$. The inequality $a_1<1/2\zeta$ or $\zeta+\zeta_1+\sqrt{(\zeta+\zeta_1)^2-1}<1/2\zeta$ represents the region in the damping plane, Figure 5, which is above the line $\zeta_1=\zeta$ and below the hyperbola $\zeta\zeta_1=1/4$. This region is marked I_B and II_B; regions I_A and II_A correspond to the underdamped case. Hence the region outside of regions I_A, I_B, II_A, and II_B which is marked as region III in the damping plane, corresponds to the region of exponential decay of all transients, and no limit cycles exist.

Depending on how the transient starts, it may approach the singular points along different trajectories. Thus, in Figure 12, if a transient starts at, say, points *1*, *2*, or *3* the motion will proceed as indicated and eventually will proceed towards the $-\alpha$ singular point along those trajectories III_{A+} which eventually are asymptotic to the lower part of asymptote 2_+, as shown. On the other hand, a transient starting at point *4* will eventually proceed to the singular point $-\alpha$ along a trajectory III_{B+} which also becomes asymptotic to asymptote 2_+. In other cases the motion will proceed to the singular point $+\alpha$ along a trajectory which ultimately becomes asymptotic to the asymptote 2_-.

It may be well to point out that the transients we are discussing are supposed to be of such a nature as to conform to the conventions we have assumed in writing the differential equations. Other types of transients may occur. Thus a transient may occur in which, although represented by a point in the phase plane, such as *2* in Figure 12 in which case the gears are supposed to be meshed, actually the gears may be unmeshed at that instant. What this means is that initially the motion will proceed along an extension of a trajectory of type II (not shown in Figure 12). However, eventually the motion must go over on a trajectory of type III, and so the essential result of exponential decay still holds.

$a_1<1/2\zeta$ is represented in Figure 13. A closer study of this figure indicates beyond doubt at least the possible existence of a limit cycle. The condition and detailed proofs of the existence, uniqueness, and (relative) stability of the limit cycle are, in this case, even lengthier than in the underdamped case. Hence the detailed proofs again will be omitted. However, the following results can be proved:

Let x satisfy the equation

$$\frac{\log\left(\dfrac{x}{a_1}-1\right)}{\log(a_1x-1)}=\frac{1}{a_1^2};\ a_1=\zeta+\zeta_1+\sqrt{(\zeta+\zeta_1)^2-1} \tag{16}$$

$$\left.0<x<-\frac{W}{\xi+\alpha}\quad\text{For lower limit curve}\right)$$

Then, if $x<1/2\zeta$, a limit cycle exists. Substituting $x=1/2\zeta$ in equation 16 results in a curve in the damping (ζ, ζ_1) plane. It can be shown that this curve is an analytic continuation of the bifurcation curve in the underdamped region between points *a* and *b* of Figure 5.

Accordingly, the region marked I_B, to the left of the bifurcation curve, Figure 5, is a region of hunting in the steady state. However, in contradistinction to the underdamped case, not all transients will end up in hunting. Only those transients which originate in the following regions in the phase plane, as shown in Figure 13, will end up in hunting:

1. The region between the lower boundary curve, the lower part of the 1_+ asymptote and the ξ axis.
2. The left boundary curve ending at intersection of upper limit curve with upper part of 1_- asymptote this upper part of the 1_- asymptote and the ξ axis.
3. The corresponding two regions above and to the right. Again it is understood that the nature of the transients should be limited according to the conventions assumed. All transients originating in regions outside those enumerated above damp out exponentially. Whether the initial transient falls in either region depends upon how it is started.

There is only one value of x which satisfies equation 16, and from this it follows that only one limit cycle can exist.

As in the underdamped case, all transients in the regions enumerated approach the limit cycle either monotonically from without, that is, with constantly increasing period and decreasing amplitude, or vice versa. Again, the amplitude of the limit cycle is greater than the reduced backlash gap 2α.

From preceding paragraphs it follows that the limit cycle is now only relatively stable, that is, with respect to trajectories in a region in the phase plane, and not with respect to all trajectories.

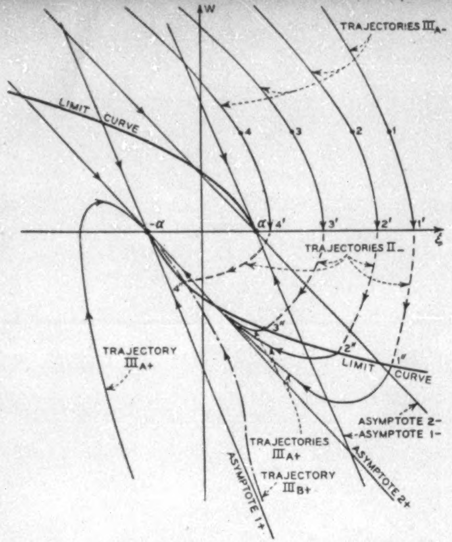
Finally if $x>1/2\zeta$, the limit points *2* and *2′* coalesce with the singular points $\xi=\pm\alpha$; $W=0$, and the limit cycle degenerates into the ξ-axis strip, $-\alpha\leq\xi\leq\alpha$, and, as in the underdamped case, the limit case of hunting or quasi-hunting results. This corresponds to the region marked II_B in the damping plane, that is, the region between the bifurcation curve, the hyperbola $\zeta\zeta_1=1/4$, and the line $\zeta+\zeta_1=1$ in Figure 5. The essential significance of a point on the bifurcation curve to which correspond a pair of values ζ, ζ_1 is that for these values there occurs a fundamental transition which can be illustrated thus:

$$\begin{tikzcd}
\text{stable singularity} \arrow[r] \arrow[dr] & \text{unstable singularity} \\
& \text{stable limit cycle} \\
\text{stable singularity} \arrow[r] \arrow[ur] & \text{unstable singularity}
\end{tikzcd}$$

Poincare, in studying the case:

$$\begin{tikzcd}
& \text{unstable singularity} \\
\text{stable singularity} \arrow[ur] \arrow[dr] & \\
& \text{stable limit cycle}
\end{tikzcd}$$

for a certain critical value of a parameter λ, has designated this phenomenon by the term "bifurcation." In our case, we are dealing with two critical parameters instead of one, and accordingly, it seems appropriate to designate, after Poincare, the curve separating regions I from II as a "bifurcation curve." Likewise, the curve, part hyperbola and part straight line, which separates the regions II and III may be designated as a quasi-bifurcation curve.



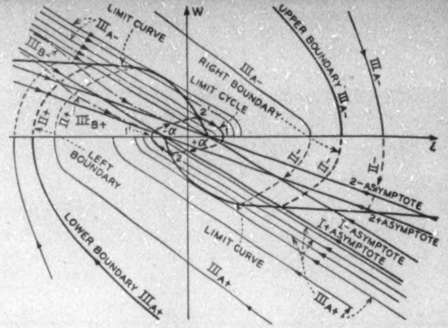


Figure 12. Types II and III trajectories in phase plane ($\zeta_1>1$, $a_1>1/2\zeta$)

Arrows indicate increasing time. Singular (nodal) points $\xi=\pm\alpha$, $W=0$. Curves are not drawn to scale

Figure 13. Trajectories and limit cycle in plane ($\zeta_1>1$, $a_1<1/2\zeta$). Limit points: 2 and 2′, limit cycle: 1–2–1′–2′–1

Arrows indicate increasing time. Singular (nodal) points at $\xi=\pm\alpha$, $W=0$. Curves are not drawn to scale

Incidentally, in the limit as $\zeta\to 0$, $\zeta_1\to\infty$, the bifurcation curve tends to the hyperbola $\zeta\zeta_1=1/8$.

Summary

The damping plane, Figure 5, may be divided into three regions, the first two of which are further subdivided, as follows:

Region I. To left of bifurcation curve; hunting in the steady state

A. For all transients.

B. For transients originating in regions in the phase plane as discussed previously.

Region II. Between bifurcation and quasi-bifurcation curve; quasi-hunting

A.
B. } As for Region I

Region III. To right of quasi-bifurcation curve All transients damp out exponentially.

Again, all of the above results hold so long as there is any finite amount of backlash. The actual value of the backlash gap enters merely in determining the amplitude of hunting, the ratio of successive increasing periods in the case of quasi-hunting, and so forth as in the under-damped case.

Perhaps the most outstanding result of this study is that in the case when a finite amount of backlash is present, viscous damping is absolutely necessary to stabilize the system. Indeed, with no viscous damping at all, the amplitude of the steady-state hunting tends to infinity, no matter how much effective error-rate damping may be present, provided only that this amount is finite.

In other words, the system cannot be stabilized with pure error-derivative control. This is not at all the case for a system without backlash.

If hunting is to be avoided at all, the (ζ, ζ_1) point, Figure 5, must be to the right of region I. If, in addition, the seemingly new phenomenon of quasi-hunting is also to be avoided, the (ζ, ζ_1) point must be situated in region III.

It should be remarked that while theoretically exponential decay in regions I_B and II_B is possible if the transient originates in certain regions of the phase plane, this is only true if no other disturbances occur until the transient damps out completely. However, as the transient is just about to be damped out, any small disturbance may throw it into the region in the phase plane which is characterized by hunting or quasi-hunting. Since the limit cycle is stable relative to all other trajectories, it will take relatively larger disturbances to produce the opposite effect. Practically, this means that if the damping ratios ζ and ζ_1 correspond to any point in regions I and II, all transients will generally end up in hunting and quasi-hunting respectively in the steady state.

Finally, it may be added that all of these purely theoretical results were confirmed completely by the results of the electronic analyzer, as was discussed elsewhere in this paper.

A Wide-Range Adjustable-Speed Drive

A. G. CONRAD
MEMBER AIEE

E. R. TRIBKEN
STUDENT MEMBER AIEE

Synopsis: This paper describes the theory and characteristics of a drive which provides a wide range of adjustable speeds. The ratio of the maximum to minimum useful speeds attainable is approximately 20-to-1. The system provides high starting-torque, relatively high efficiencies and rapid deceleration through regenerative braking. The drive uses d-c series motors and generators and it can be assembled from standard equipment.

Principle of Operation

WHEN a series motor is supplied with a voltage which is proportional to its current, its speed is essentially constant for various values of output power. The operating speed is determined by the rate of change of the applied voltage with change of input current. A circuit for supplying such voltages to a series motor is shown in Figure 1. The two series machines 1 and 2 are driven at constant speed. Their combined output is used to drive the series motor 3 which provides constant adjustable-speed for the load. If the ratio of the field strengths of the series machines 1 and 2 can be held constant, and the polarities of these machines are unaltered, the voltage supplied to the series motor 3 will vary with load such that the speed of this motor will be kept essentially constant for different values of developed torque. The magnitude of this ratio is determined by the adjustment of the rheostat R_c. The setting of the switch S_1 can be used to change the polarity of the machine 2—thus converting it from a generator to a motor or vice versa.

The voltage applied to the motor 3 can be made equal to either the sum or the difference of the terminal voltages produced by machines 1 and 2. High speeds are obtained by setting the switch S_1 so that the voltages produced in the machines 1 and 2 are aiding. For low speeds the field of machine 2 is adjusted so that it behaves as a motor, thereby reducing the voltage supplied to the motor 3. Minimum speed is obtained when the machines 1 and 2 are producing voltages which are essentially equal and opposite. Maximum speed is obtained when the fields of machines 1 and 2 are fully excited and their voltages are aiding. Intermediate speeds are obtained by proper setting of the rheostat R_c and the switch S_1.

For a given direction of rotation of the motor a reversal of the field of machine 3 through the switch S_2 will change the behavior of this machine from motor action to generator action and vice versa. Regenerative braking can be accomplished if the field strengths of machines 1 and 2 are adjusted so that the power received by machine 2 from machine 3 exceeds that which is delivered by machine 1 to machine 3.

Characteristics

The speed characteristics of this drive are attainable from an analysis of the circuit shown in Figure 1. The constants shown in Table I will be used in the analysis.

The sum of the voltages around the circuit is

$$Eg_1 \pm Eg_2 - I\left(Ra_1+Ra_2+Rf_1+\frac{Rf_2R_c}{Rf_2+R_c}\right) = Eg_3+I(Ra_3+Rf_3) \quad (1)$$

Let $(Ra_1+Ra_2+Rf_1+Ra_3+Rf_3)=R$

$$\therefore\ Eg_1 \pm Eg_2 - I\left(R+\frac{Rf_2R_c}{Rf_2+R_c}\right) = Eg_3 \quad (2)$$

$$Eg_1 = K_1'\phi_1 Ng = K_1 I Ng \quad (3)$$

$$Eg_2 = K_2'\phi_2 Ng = K_2(I-I')Ng \quad (4)$$

$$I-I' = \frac{IR_c}{Rf_2+R_c} \quad (5)$$

$$Eg_2 = K_2\frac{R_c}{Rf_2+R_c}\ INg \quad (6)$$

$$Eg_3 = K_3'\phi_3 N_3 = K_3 I N_3 \quad (7)$$

Substituting equations 3, 6, and 7 in equation 2

$$K_1 I Ng \pm K_2\frac{R_c}{Rf_2+R_c} INg - I\left(R+\frac{Rf_2R_c}{Rf_2+R_c}\right) = K_3 I N_3 \quad (8)$$

Solving for N_3

$$N_3 = \frac{Ng\left(K_1 \pm K_2\frac{R_c}{Rf_2+R_c}\right) - R - \frac{Rf_2R_c}{Rf_2+R_c}}{K_3}$$

$$= K - \frac{R_c}{Rf_2+R_c}\left(Rf_2 \pm \frac{K_2}{K_3}Ng\right) \quad (9)$$

when

$$K = \frac{K_1}{K_3}Ng - \frac{R}{K_3}$$

It is evident from equation 9 that for a given setting of the rheostat R_c the speed of the motor 3 is constant and it is independent of current and therefore independent of the torque developed. Equation 9 also shows that the motor has a definite speed for each setting of R_c and consequently it is an adjustable-speed drive.

The preceding analysis did not take into account the effects of nonlinearities

Table I

	Machine 1, Generator	Machine 2, Motor or Generator	Machine 3, Motor

2. Series motor or generator
3. Series motor

of the machines involved. Some nonlinear effects will result from residual magnetism for low values of power output. Saturation also will produce nonlinear effects when the current in any of the three machines is large. These effects are predictable from relations defined in equation 2 as follows:

1. The voltages Eg_1 and Eg_2 have components which are caused by the residual magnetism of their respective machines. These components are essentially constant and become significant parts of the generated voltages of machines 1 and 2 at low values of current. For the case when Eg_2 opposes Eg_1 and Eg_2 is smaller than Eg_1, the total output voltage will decrease with a decrease of current at a greater rate than it would for linear conditions. This results in a reduction of speed as the current decreases. For high-speed settings of switch S_1, machines 1 and 2 will tend to act like a constant-voltage supply at low values of current. Therefore in the low-torque high-speed range a decrease in load results in a slight increase in speed.

2. The iron of machines 1 and 2 will saturate at high values of current. This produces a lower rate of increase of the total voltage output with an increase in current and thereby causes the speed of the motor to decrease with an increase of load.

3. The generated voltage of machine 3 will possess some degree of nonlinearity. Generally, this tends to counteract the speed changes due to the nonlinearities of the generated voltage of machine 1 and 2.

4. Brush resistances increase with a decrease of current causing a small change in the total resistance of the circuit. The effects of this slight increase in resistance are negligible except when the output voltage of machines 1 and 2 is small. For this condition the motor speed will decrease slightly with a decrease of current.

The reasons for a variation in the speed as the load is changed indicate several counteracting factors. The net result of these factors can be quite different for different machines. The optimum characteristics of this system are obtained only through a design such that the nonlinear effects are minimized. While linear units are desirable, considerable nonlinearity is tolerable if it is properly controlled.

The analysis of this unit thus far has dealt with only conditions of steady-state operation. A complete study of the transient characteristics of the unit is beyond the scope of this paper and is unnecessary since experimental results show that the system is stable. Under certain conditions of operation with generators which are not identical, the total output voltage of machines 1 and 2 may attain certain values such that an increase of current produces a decrease in output voltage and then further increases in current may produce an increase in the voltage. This condition can cause instability in the motor. Generally, an increase in the values of the series resistances will add stability.

Typical ratings for a suitable drive are:

	Horsepower	Volts
Motor—3	10	220
Generator number 1	5	110
Generator number 2	5	110
Prime mover	10	
Total	30	

Performance and Conclusions

The performance of this drive is revealed in Figure 2. This unit has a useful speed range of 20-to-1. Speed regulation for various speed adjustments is:

Speed, Rpm	Speed Regulation, Per Cent
100	13.3
1,000	0
1,800	9.7

These data were taken on standard equipment available in Dunham Laboratory of Electrical Engineering at Yale University. Machines 1 and 2 had similar ratings, but they did not have suitable ratings to match exactly those of machine 3. No attempt was made to compensate for the nonlinearities present in the machines.

The departures from constant speed in the characteristics shown in Figure 2 are caused by the nonlinearities in the machines. With suitable compensation, it should be possible to build a drive which will have less speed variation throughout the entire range of speed adjustment. Such provisions could extend the range.

If the resistance Rf_3 is small, R_c must have a low ohmic value. The design of such a rheostat may, under certain conditions, be difficult. This undesirable feature could, in some cases, limit the application of the drive.

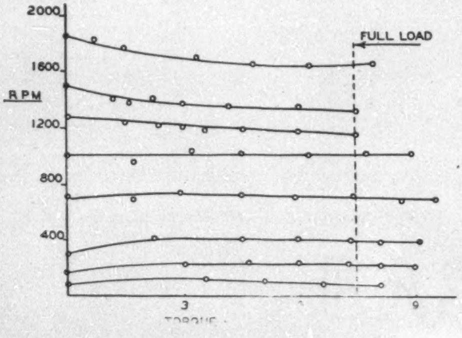

Figure 2. Characteristics of the motor 3 when operating in the circuit of Figure 1

No Discussion

Equipment Used With Coaxial Cable for Carrier Current Installation on Power Lines, Line Tuning. Sutton...........................44–8; disc. 48
Equivalent Circuits for Power-Flow Studies. Ward..373–80; disc. 380
Erythemal Energy, Measurements of. Scott....725–29
Evaluation of the Stability of the Welding Arc, Instrumentation for the. Winsor, Schetky, Wyant..525–33
Exciter Voltage Regulating System as Determined by Electrical Analogy, The Transient Behavior of the Two-Stage Rototrol Main. Carleton.......59–63
Expanded Scale A-C Voltmeter, A New. Millar..641–3
Experience With 4-Kv Primary Network Systems in the Washington Area, Design and. Lank..712–16; disc. 716
Experimental Study of Speed-Torque Curves, Dynamic Braking Control of D-C Series Motors—. Heumann..................................560–4
Experimental Test Procedures and Methods of Analysis of Results to Research Problems in Magnetic Recording, Application of. Thompson.......407–17

F

Facsimile Transmission Speed, Considerations on. Burkhard.......................418–23; disc. 423
Factor of Unbalanced Sinusoidal 3-Phase Circuits, The Vector Power. Lamb, Brandt.............507–09
Fault Currents, Rectifier—II. Herskind, Schmidt, Rettig..........................242–51; disc. 251
Fault Limiting Means on High Interrupting Capacity Controllers, The Use of Air-Core Reactors as. Leitch.......................469–74; disc. 474
Faults and Power Swings, Graphical Method for Estimating the Performance of Distance Relays During. Warrington..................608–20; disc. 620
Feedback, Analytical Determination of Characteristics of Magnetic Amplifiers with. VerPlanck, Finzi, Beaumariage.............................565–70

Feed-Back Control Systems with Particular Reference to Backlash, Instrument Inaccuracies in. Marcy, Xachter, Zauderer........................778–88
Field Components of Circular Filaments and Solenoids, Formulas and Tables for the Calculation of the Magnetic. Grover........................665–75
Field Fluxes of the Shaded-Pole Motor, The. Kimberly........................273–7
Filaments and Solenoids, Formulas and Tables for the Calculation of the Magnetic Field Components of Circular. Grover........................665–75
Film Conditions on Commutation, Effects of Commutator Surface. Lynn, Elsey.....106–12; disc. 112
Fluxes of the Shaded-Pole Motor, The Field. Kimberly........................273–7
Formulas and Tables for the Calculation of the Magnetic Field Components of Circular Filaments and Solenoids. Grover........................665–75
Fourier Coefficient Harmonic Analyzer, A New. Charp........................644–9; disc. 649
Frames, Stationary Networks and Transmission Lines Along Uniformly Rotating Reference. Kron........................690–6
Frequencies and Under Changing Temperature, The Measurement of Dielectric Loss at High. Whitehead, Rueggeberg........................520–4
Frequencies, Loss Measurements Made on Underground-Cable Overhead-Conductor 132-Kv Transmission Line at Carrier Current. Cornelius, Storer........................597–601
Frequency Cables, Heating of Radio-. Macalpine........................283–8
Frequency Cables, The Power Rating of Radio-. Mildner........................289–98; disc. 298
Frequency Heating Equipment, Reduction of Interference from Radio-. Klingaman.718–24; disc. 724
Frequency Response Curves, Control Chart Methods Applied to. Mundel........................424–7
Function Loci for Servomechanism Components and Systems, Graphical Determination of Transfer. Thomas, Easton...............307–14; disc. 314
Fundamental Theory of Inherent-Overheating Protection Under Running Overload Conditions. Veinott, Schaefer........................266–70; disc. 270
Fundamentals of D-C Controlled Reactors with Resistive Load, Some. Storm............188–94; disc. 194

G

Gas-Filled Cable Impregnated with Extra-High-Viscosity Oil, High-Pressure. Sticher, Doan, Atkinson, Meyerhoff...............336–45; disc. 345
Gas Turbine Power Plant, A 3,000-Horsepower. Haverstick........................458–60
Gas Turbines for Power Generation and Other Applications, Two. Howard............461–5; disc. 465
Gas Turbines in Stationary Power Generation. Hague........................467–8
Generation and Other Applications, Two Gas Turbines for Power. Howard............461–5; disc. 465
Generation, Commutation of D-C Machines and Its Effects on Radio Influence Voltage. Motter........................491–5; disc. 495
Generation, Gas Turbines in Stationary Power. Hague........................467–8
Generators, A Semiempirical Approach to Voltage Dip—with Suddenly Applied Loads on A-C. Rosenberg........................160–6; disc. 166
Generators, Solid Short Circuit of D-C Motors and. Linville, Ward...............119–23; disc. 123
Geometric Loci of the Synchronous Tie, The. Finzi, Wellard........................168–71
Graphical Determination of Transfer Function Loci for Servomechanism Components and Systems. Thomas, Easton...............307–14; disc. 314
Graphical Method for Estimating the Performance of Distance Relays During Faults and Power Swings. Warrington...............608–20; disc. 620

H

Harmonic Analyzer, A New Fourier Coefficient. Charp........................644–9; disc. 649
Heat Pump—Its Significance as a Potential Residential Electric Load, The. Bary........................1–8
Heating Equipment, Reduction of Interference from Radio-Frequency. Klingaman..718–24; disc. 724
Heating of Radio-Frequency Cables. Macalpine........................283–8
High Frequencies and Under Changing Temperature, The Measurement of Dielectric Loss at. Whitehead, Rueggeberg........................520–4
High-Pressure Gas-Filled Cable Impregnated with Extra-High-Viscosity Oil. Sticher, Doan, Atkinson, Meyerhoff...............336–45; disc. 345
High-Voltage Bushing Design for High Altitudes, A Small. Vogel, Hart........................761–4
High-Voltage Corona, Radio Influence from. Slemon........................198–204; disc. 204
High-Voltage Switching, Protection of Stations Without. (Committee Report)............226–31; disc. 231
Horsepower Gas Turbine Power Plant, A 3,000-. Haverstick........................458–60
Hydro Units, Outage Rates of Steam Turbines and Boilers and of. (Committee Report)......450–7
Hy-Therm Copper—An Improved Overhead-Line Conductor. Hickernell, Jones, Snyder..22–7; disc. 27

I

Impregnated with Extra-High-Viscosity Oil, High-Pressure Gas-Filled Cable. Sticher, Doan, Atkinson, Meyerhoff...............336–45; disc. 345
Improvements to Oklahoma City Primary Network. Brady...............701–02; disc. 702
Incandescent Lamps, Saving Time in Testing Life of. Purcell........................730–2
Indicator, Polar Vector. Walker, Waynick, Sulzer........................154–9
Induction Motors, Die-Cast Rotors for. Packer........................253–60; disc. 260
(Industrial Control) The Use of Air-Core Reactors as Fault Limiting Means on High Interrupting Capacity Controllers. Leitch......469–74; disc. 474
(Industrial) Dynamic Braking Control of D-C Series Motors—Experimental Study of Speed-Torque Curves. Heumann........................560–4
Industrial Plants Prefer Diesel-Electric Switching Locomotives. Woods........................697–700
(Industry) Selection of Electric Drives for Looms. Demartini, Lukens........................349–56
Influence from High-Voltage Corona, Radio. Slemon........................198–204; disc. 204
Influence Voltage Generation, Commutation of D-C Machines and Its Effects on Radio. Motter........................491–5; disc. 495
Inherent-Overheating Protection Under Running Overload Conditions, Fundamental Theory of. Veinott, Schaefer........................266–70; disc. 270
Installation on Power Lines, Line Tuning Equipment Used With Coaxial Cable for Carrier Current. Sutton........................44–8; disc. 48
Instrument Inaccuracies in Feed-Back Control Systems with Particular Reference to Backlash. Marcy, Yachter, Zauderer........................778–88
Instrument Servomechanisms, Damper Stabilized. Hall........................299–306; disc. 306
Instrumentation for the Evaluation of the Stability of the Welding Arc. Winsor, Schetky, Wyant....525–33
(Instruments) A New Expanded Scale A-C Voltmeter. Millar........................641–3
(Instruments) A New Thermal Volt-Ampere Demand Meter. Douglass, Morong.........79–83; disc. 83
(Instruments) An Electro-Optical Shutter for Photographic Purposes. Zarem, Marshall, Poole..84–91
(Instruments) Automatic Range-Adjusting Radiosonde Recorder. Beggs........................602–07
(Instruments) Polar Vector Indicator. Walker, Waynick, Sulzer........................154–9
(Instruments) Surge Protection in a Modern Watt-Hour Meter. Busch, Williams......74–7; disc. 77
(Insulated Conductor) High-Pressure Gas-Filled Cable Impregnated with Extra-High-Viscosity Oil. Sticher, Doan, Atkinson, Meyerhoff........................336–45; disc. 345
(Insulated Conductor) The Thermal Movement of Moisture in Soil. Mickley........330–3; disc. 333
(Insulated Conductors) Transformer Manholes and Vaults: Design and Ventilation. Porter...534–9
Insulation, Methods for Determining the Effects of Contaminants on Electrical. Mathes, Sieffert, Walker, Lindsey...............113–18; disc. 118
Insulation Protection in the Operation of Power Transformers, Controlled Temperature and. Satterlee, Reed........................753–8; disc. 759
Insulators for Pole Lines, Rubber. Wheeler, Markley........................195–7
Interference from Radio-Frequency Heating Equipment, Reduction of. Klingaman..718–24; disc. 724
Interrupting Capacity Controllers, The Use of Air-Core Reactors as Fault Limiting Means on High-. Leitch........................469–74; disc. 474
Investigation on a Rural Distribution System, Lightning. MacCarthy, Stann, Edge, McKinley........................428–37; disc. 437
Iron Losses in Series Motors, Armature. Chang, Karr........................262–4; disc. 264

J

Joints by Means of a Bolometer, Detection of Overheated Transmission Line. Leslie, Wait........................64–8; disc. 68

DEPENDABLE electric service in suburban and rural areas is of increasing importance because of the addition of many new electrical appliances to the home and the continued expansion of farm electrification. Power outages seriously inconvenience the residential consumer and may cause heavy loss of produce on the farm. Moreover, rising labor and automotive costs have increased utility operating expenses to a point where an excessive number of service trips no longer can be tolerated. It is, therefore, of vital importance that overcurrent protection for suburban and rural circuits be applied properly to yield the greatest possible reduction in the number and extent of outages.

In recent years, much emphasis has been placed on the application of automatic reclosers and distribution fuse cutouts for overcurrent protection of outlying distribution circuits. This paper discusses an analytical method for determining co-ordination of reclosers with series fuses and presents field test data which substantiate this method.

Analysis of Recloser-Fuse Co-ordination

The primary function of any recloser in a distribution circuit is to clear, by instantaneous opening, all temporary faults before fuses blow and, by time-delay opening, to provide for clearing all permanent faults occurring in its zone of protection.

A recloser, in order to accomplish this function, must have reliable characteristics capable of providing proper recloser-fuse co-ordination irrespective of ambient temperature changes, and of providing co-ordination with adjacent ratings of reclosers in series.

It is realized that with a recloser and a fuse in series with a fault, each operation of the recloser will cause heating and cooling of the fuse, with the result that the total heat input required to melt the fuse link during successive recloser operations cannot be determined directly from the published melting time–current characteristics of the fuse link.

In preparing a circuit co-ordination study, the effective heating and cooling of the fusible element must be evaluated properly in order to prevent unnecessary fuse blowing or misperformance by recloser lockout.

The following is a procedure that has been established for determining the fuse ratings that will co-ordinate with a particular rating of recloser. This basic procedure is applicable to all types of reclosers to be operated in series with fuses

This procedure includes operating and manufacturing variables of each device:

1. Total variation in recloser tripping characteristics.
2. Total heat input to a fuse link during the time required for the recloser to open and interrupt the fault current.
3. Twenty-five per cent allowance in melting time–current characteristics of fuse to factor operating variables, such as preloading, and progressive melting of fusible element and strain wire.
4. Cooling of the fuse link during intervals that the recloser is open.

Each of the foregoing factors will be considered separately to show how it applies.

Total Variation in Recloser Tripping Characteristics

Referring to Figure 1, it will be noted that the instantaneous characteristic *A* of the recloser is plotted to maximum test points. Hence, all instantaneous opening operations of the recloser will fall either on or below this curve. It serves as a basis, therefore, for determining the co-ordination of the recloser to the melting time–current characteristics of fuses and, hence, for assuring protection of load-side fuses during the first and second (instantaneous) opening operations.

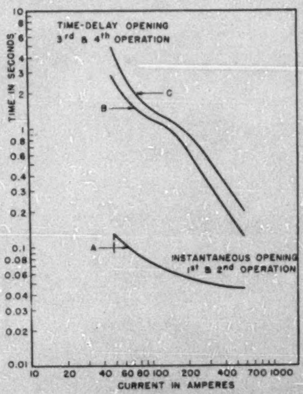

Figure 1. Characteristics of 25-ampere *FR-1* recloser

Paper 49-128, recommended by the AIEE Switchgear Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer General Meeting, Swampscott, Mass., June 20–24, 1949. Manuscript submitted March 22, 1949; made available for printing May 2, 1949.

G. G. AUER is located in Schenectady, N. Y., R. A. BRANFLICK is located in Pittsfield, Mass., and L. J. WOODWARD is located in Philadelphia, Pa.; all with the General Electric Company. W. C. McKINLEY is with the Central Electric Cooperative, Inc., Parkers Landing, Pa.

Figure 3. Test circuit diagram

The time-delay characteristic *B* and *C* of the recloser is plotted to both minimum and maximum test points, and, hence, all time-delay opening operations of the recloser will fall within the band of variations.

The minimum time-delay curve *B* serves as a basis for determining the co-ordination of the recloser to the total-clearing characteristics of fuses, to assure that permanent faults will be cleared by load-side fuses during the third or fourth (time-delay) opening operation before the recloser locks open.

The maximum time-delay curve *C* serves as the basis for determining the ability of the recloser to prevent operation of overcurrent relays or fuses on the source side of the recloser during its third and fourth (time-delay) opening operations to lock open.

Total Heat Input to a Fuse Link During the Time Required for the Recloser to Open and Interrupt the Fault Current

The time–current characteristic curves of a recloser can be factored to include heating of a fuse link when comparing with time–current characteristics of fuses.

Let us assume that we wish to prevent a fuse from blowing during two instantaneous openings of the recloser when clearing temporary faults. We must consider the total amount of heat received by the fuse during these two instantaneous openings of the recloser. By doubling each time value on the instantaneous characteristic curve *A*, we arrive at a modified curve which represents the total length of time that short-circuit current flows through the fuse link during the first two recloser openings.

Assuming a permanent fault beyond the fuse, proper co-ordination requires that the fuse melt before the recloser locks open. In this case, we must determine the minimum heat input to the fuse link during the two instantaneous plus two time-delay openings of the recloser, to be sure that it is sufficient to melt the fuse before the recloser locks open. By doubling the time values on both the instantaneous characteristic curve *A* and the minimum time-delay characteristic curve *B* and adding the two together, we arrive at a modified curve which represents the minimum length of time that short-circuit current flows through the fuse link during four recloser operations.

In co-ordinating the recloser with a source-side fuse, it is necessary that the four operations of the recloser to lock open will not cause partial melting of the fuse. In this case, our modified curve would be equal to the sum of two instantaneous openings, curve *A*, plus two time-delay openings, curve *C*. This final curve then represents the maximum or total length of time that short-circuit current is permitted to flow through the fuse link.

Allowance of 25 Per Cent in Melting Time–Current Characteristics of Fuses to Factor Operating Variables

The time–current characteristic curves of fuse links are based upon no initial load. Whenever fuses are preheated by load current, a 15 per cent reduction in melting time should be taken into consideration. An additional reduction of 10 per cent must also be included to take into account the progressive melting of the fusible element and the strain wire.[1] Therefore, the over-all factor of safety should be a 25 per cent reduction of the melting time–current characteristic of the fuse to assure that the fuse will not be

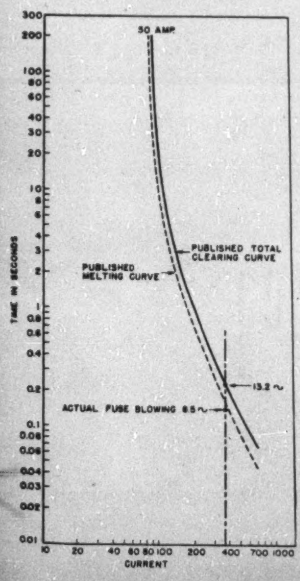

Figure 5 (left). Time-current characteristics of 50-ampere fuse link

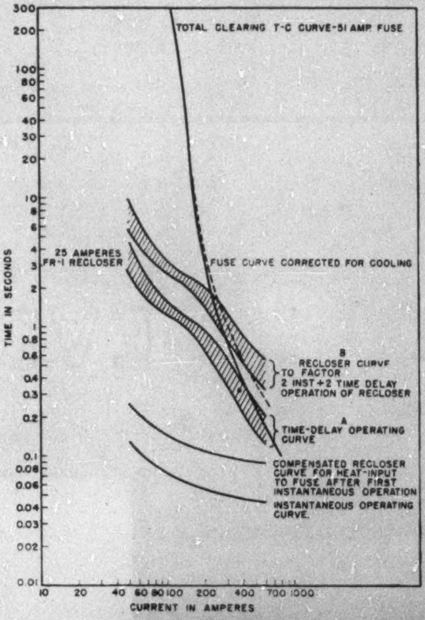

Figure 6 (right). Analytical co-ordination method of comparing characteristics of reclosers and fuses partially melted by the fault current during any instantaneous openings of the recloser.

Cooling of the Fuse Link During Intervals that the Recloser is Open

Each successive opening of the recloser is followed by an interval of approximately 40 cycles before reclosing. During this interval there is no current flowing through the fuse, and, consequently, the fusible element has an opportunity to cool. As a result, the fuse will be somewhat slower in melting than in the case where no cooling is permitted. The additional increment of time for cooling, which can be calculated, must be added to the melting and total clearing time–current characteristics of the fuse.

Test Circuit

This basic procedure for recloser-fuse co-ordination was substantiated by a series of field tests performed on a typical rural distribution circuit located on the Central Electric Cooperative System at Parkers Landing, Pa.

The circuit selected for these tests, Figure 2, was a 7,200-volt single-phase branch line approximately 25 miles long with three sectionalizing points. The first sectionalizing point, where the single-phase line tapped off the main 3-phase line, was six miles from a 900-kva substation. The maximum calculated fault current at this location was 430 amperes line-to-neutral. The second sectionalizing point was 12 miles from the first location; the calculated fault current was 140 amperes. The third and last sectionalizing point was eight miles from the second location, and the calculated fault current at this point was 90 amperes.

To perform these tests in daylight hours under maximum generation on the system and under normal voltage and load conditions, a test circuit was used, as shown in Figure 3. This permitted application of faults with a solid-blade enclosed cut-out and clearance of fault by fuse, or by recloser operation without any prolonged service interruption.

This test-circuit equipment was portable and was moved from one location to another.

Figure 3(B) shows the two enclosed-type cutouts of Figure 3 mounted side by side on the test board at location *1*, Figure 3(A).

One cutout was fused for the purpose of testing the operation of fuses in series with the recloser. The other cutout with the solid disconnecting blade was used as a switch to apply the fault.

A 300/5-ampere current transformer, mounted on the test board below the cutouts, was used to energize the current element in the oscillograph.

Two standard distribution transformers, 7,200/120-240 volts, were used to provide voltage traces on the oscillogram for sequential operation study; one was connected on the source side of the re-

closer, and the other was connected to the load side of the recloser. Because of congestion on the pole and also to improve safety to the linemen, these transformers were omitted from the tests at locations *2* and *3*. A 100-cycle tuning fork was used to record the reference trace at these latter locations.

The ratings of the reclosers used at test locations *1*, *2*, and *3* were selected on the basis of the fault current and load current, resulting in a 25-ampere recloser at location *1*, a 15-ampere recloser at location *2*, and a 10-ampere recloser at location *3*.

The ratings of fuses used in these tests were selected on the basis of the procedure previously described for recloser-fuse co-ordination which took into consideration heating and cooling of the fuse link.

At location *1*, with the test circuit as shown in Figures 3 and 3(A), a 50-ampere fuse link was installed in cutout *B*, to be tested for co-ordinated series operation with the 25-ampere recloser.

Recloser-Fuse Co-ordination Test

At a predetermined time established by the oscillographer, cutout *C* was closed to apply a permanent fault from line-to-neutral on the test circuit.

The oscillogram in Figure 4 shows the magnitude of fault current, the sequence of operation, and the cycle timing.

The measured fault current was 370 amperes. The 25-ampere recloser made its first instantaneous opening in 2.5 cycles; reclosed after 44 cycles; made a second instantaneous opening in 2.5 cycles; and reclosed after 41 cycles for its first time-delay operation. This first time delay of the recloser allowed the 50-ampere fuse to blow in 8.5 cycles, thereby clearing the permanent fault from the circuit.

Referring to Figure 5, the standard published total clearing time–current characteristic of the 50-ampere fuse shows that 370 amperes would melt this link in a maximum time of 13.2 cycles. However, because heat was applied for two instantaneous openings of 2.5 cycles each with 44- and 41-cycle cooling intervals, the fuse cleared the circuit in 8.5 cycles instead of 13.2 cycles during the third (time-delay) operation of the recloser.

This test was repeated twice more at this location using the same rating fuse. The results substantiated the first tests; that is, the final duration of fault current to blow the fuse was 8.5 cycles and 8 cycles, respectively.

This approximately 36-per-cent difference in fuse curve time and actual fuse blowing time emphasizes the importance of the basic procedure in evaluating the heating of a fuse link when co-ordinating reclosers to fuses.

To go a step further in this study of fuse heating plus cooling with respect to its clearing time, a 51-ampere co-ordinating link (equivalent to a *75N* fuse) was selected for the next test at location 1. Taking into consideration the heating and cooling of this link, it should blow during the second time-delay operation of the

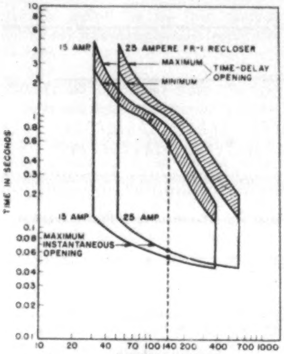

Figure 9. Comparison of characteristics of 25-ampere and 15-ampere reclosers to determine co-ordination between adjacent ratings of reclosers connected in series

25-ampere recloser; that is, the recloser should make two instantaneous openings, one complete time-delay opening, and then during the second time delay, as a result of previous heating, the fuse will blow before the recloser locks open.

Curve *A*, Figure 6, which neglects heating and cooling of the fuse link, indicates that the recloser will operate on time delay to clear the 370-ampere fault before the 51-ampere fuse blows. However, curve *B*, which factors the heat input to the fuse, indicates that before the recloser can complete its second time-delay opening, the fuse will melt and clear the fault.

The oscillogram shown in Figure 7 substantiates this latter analysis; that is, the recloser made two instantaneous openings in two cycles each, one time-delay opening in 19.5 cycles, and, after reclosing to the second time-delay operation, the fuse cleared the circuit in 17.5 cycles—making a total of 41 cycles which compares favorably with the 0.73 second (44 cycles) of the corrected fuse curve of Figure 6.

The oscillogram shown in Figure 8 is a repeat test with another 51-ampere fuse. The recloser made two instantaneous openings in two cycles and 2.5 cycles respectively, plus one time-delay opening in 19 cycles, and, after reclosing to the second time-delay operation, the fuse cleared the circuit in 16 cycles—making a total of 39.5 cycles which also compares favorably with the 0.73 second or 44 cycles indicated by the corrected curve in Figure 6.

These tests also indicate that neglecting the heating and cooling factors in a recloser-fuse co-ordination study can result in misperformances on actual installations which will cause unnecessary and prolonged circuit outages.

Recloser-to-Recloser Co-ordination Test

In reference to recloser operation, proper distribution-line fault sectionalizing depends upon the ability of one recloser to co-ordinate with its adjacent rating and all other reclosers within its range of protection. With repetitive operation of each recloser, the smallest rating adjacent to a permanent fault always must lock open to isolate the fault, just as with recloser-fuse co-ordination, a permanent fault on the load side of the fuse must always blow the fuse before the recloser locks open.

In co-ordinating adjacent ratings of reclosers having an operating sequence which involves both instantaneous and time-delay operations, two or more reclosers may operate instantaneously before the smallest rating adjacent to the permanent fault operates twice on time delay and locks open. This is inherent in all types of reclosers which operate instantaneously and arises from the fact that the instantaneous openings of the larger ratings may be faster than the time-delay opening of the smallest rating. However, if the time-delay openings are sufficiently accurate, co-ordination is not affected, because the smallest rating will always lock open and permit the larger rating to reset automatically to normal position.

It is evident that operations of reclosers other than the one nearest the fault could be prevented by decreasing the speed of the instantaneous openings. However, this seriously limits the ability of the recloser to prevent fuse blowing and conductor or apparatus damage and, therefore, greatly reduces its protective value. Figure 9 shows the opening characteristic curves of a 25-ampere and a 15-ampere recloser connected in series. With fault current of 140 amperes, both reclosers will open, either simultaneously or consecutively, at or below their curve of maximum time for instantaneous opening. After each has made its two instantaneous openings, only the smaller rating recloser will operate twice more on its time-delay characteristics to lock open. The oscillogram shown in Figure 10 shows the proper co-ordination of 25-ampere and 15-ampere reclosers connected in the circuit at locations *1* and *2*

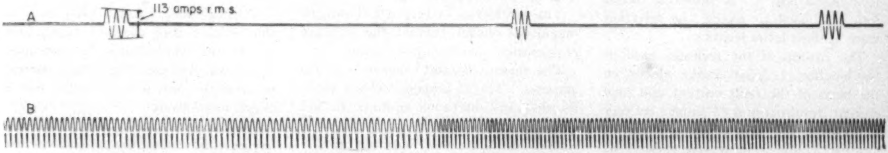

Figure 10. Oscillogram (in two parts) showing proper co-ordination of 25-ampere and 15-ampere reclosers connected in series

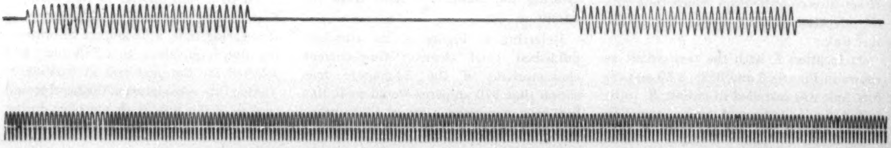
Curve A—Short-circuit current, 133 rms amperes

Curve B—Timing wave, 100 cycles



respectively, with a fault current of 133 amperes on the load side of location *2*. The circuit diagram is shown in Figure 3(A).

It is not possible to determine the exact sequence of operations, in view of the fact that the potential transformers could not be installed at location *2*. However, three instantaneous openings and two time-delay openings were indicated on the film.

Bearing in mind that neither recloser can operate on its time-delay characteristic until it has previously made two instantaneous openings, the five openings shown on the film might be analyzed as follows:

The first opening was made by the smaller rating (15-ampere) recloser alone; the second opening was a simultaneous opening of both 15-ampere and 25-ampere reclosers; the third opening was made by the 25-ampere recloser alone; and the fourth and fifth openings were time-delay openings of the 15-ampere recloser which locked open. The co-ordination between reclosers is accomplished during time-delay operation, and, to be successful, reliable characteristics must be inherent in the design.

The oscillogram shown in Figure 11 shows the test results with the 25-ampere recloser at location *1* in series with a 15-ampere recloser and a 30-ampere fuse at location *2*, and a fault applied on the load side of the fuse. The fault current was 133 amperes at this location. This is a typical application for a fused branch line beyond two reclosers in series. The objective, in this case, is to protect the branch fuse during the two instantaneous openings of the source-side recloser nearest this fuse and to blow the fuse before the recloser locks open. After the nearest recloser has completed two operations, instantaneous openings of other reclosers closer to the source may cause the fuse to blow.

However, the original objective has been accomplished and co-ordination is in no way affected.

This film shows three instantaneous openings, indicative of simultaneous and consecutive openings of both reclosers, and one time-delay opening which allowed blowing of the 30-ampere fuse link.

The second instantaneous opening shows clearance of the fault in one cycle, which is considerably faster than characteristic curves of either recloser indicate for 133 amperes of fault current. This fast opening, upon further investigation, was believed to have been influenced by inrush current after the 40-cycle open period. Between locations *1* and *2* were several large strip coal mines and a pumping station, each having a large number of motors in operation.

In analyzing this film, there is indication that the 25- and 15-ampere reclosers opened simultaneously when the 133-ampere fault was first applied. The 25-ampere unit reclosed first, thus energizing the line to location *2*. Inrush current to motor load in this section was of sufficient magnitude to cause partial pickup of the 25-ampere recloser. The 15-ampere recloser then reclosed; thus, the fault current added to the inrush current through the 25-ampere recloser, which was in partial pickup position, tripped in the first cycle of fault current. The 15-ampere recloser did not open in this second operation shown on the film. After this fast opening, the 25-ampere recloser had completed two instantaneous openings and would reclose on its time-delay characteristic. The 15-ampere recloser had made only one instantaneous opening; therefore the third instantaneous opening on the film was the second instantaneous opening of the 15-ampere recloser. The latter recloser then reclosed on time-delay characteristics, resulting in both reclosers being on time-delay, causing the 30-ampere fuse to blow in 25.5 cycles.

This test indicated that motor inrush currents on line sections between reclosers may affect the sequence of instantaneous openings of reclosers in series. This test also proved that possible difference in the instantaneous opening speed and variation in instantaneous opening sequence, will not affect proper co-ordination between adjacent reclosers or reclosers and fuses in clearing a permanent fault, if time-delay opening characteristics of the reclosers are dependable.

To study the performance of three reclosers in series, a 10-ampere recloser was installed at location *3*. The 15-ampere recloser was connected in series in the line at location *2;* the 25-ampere recloser was, as in the previous tests, at location *1*. Figure 3(A) shows the series connections in the 20-mile section of line.

The oscillogram of Figure 12 shows five instantaneous openings and two time-delay openings necessary to clear the permanent fault from the circuit when a 92-ampere fault current was flowing through the recloser. It is believed that the sequence of opening of the three reclosers in series as shown on the film is as follows:

The first instantaneous opening was made by the 10-ampere recloser alone; the second opening is simultaneous instantaneous operation of the 10- and the 15-ampere reclosers; the third opening is the second instantaneous operation of the 15-ampere recloser; the fourth opening is the first instantaneous operation of the 25-ampere recloser; the fifth opening is the second instantaneous operation of the 25-ampere recloser; and the sixth and

Curve A—Short-circuit current, 92 rms amperes

Curve B—Timing wave, 100 cycles

seventh openings are time-delay operations of the 10-ampere recloser which locked open.

This test proved that after each recloser had completed two instantaneous openings, it advanced to time-delay position, but only the smaller rating recloser adjacent to the fault opened on time delay and locked open to sectionalize the fault.

Discussion of Results

The data obtained in the field test show that co-ordination of reclosers with series fuses cannot be determined from direct comparison of the published characteristics of each device. However, a comparison of the test results with those obtained by the analytical co-ordination method set forth in this paper indicates that this method will provide adequate allowances for all manufacturing and operating variables to assure successful co-ordination.

Tests involving co-ordination of two or more reclosers in series show that several reclosers may perform instantaneous operations before the smallest rating of recloser adjacent to the fault locks open to sectionalize the fault. However, if the time-delay characteristics of the recloser are sufficiently accurate, dependable co-ordination of series reclosers can be obtained.

The field tests disclose that motor inrush currents on line sections between reclosers may affect the sequence of instantaneous operations of the reclosers.

Where reclosers and fuses are operated in series, the appreciable difference between published fuse characteristic curves and actual fuse clearing time, which results from intervals of heating and cooling of the fuse link during successive recloser operations, must be evaluated if successful operation is to be obtained. The analytical co-ordination method described affords a reliable means of factoring heating and cooling effect on the fuse link together with all other manufacturing and operating variables which affect co-ordination.

Discussion

John B. Gmeiner (The Commonwealth and Southern Corporation, Jackson, Mich.): The author's paper presents a compilation of knowledge gained over the past few years in the application of oil circuit reclosers and brings out some facts that have not always been fully recognized.

The operation of reclosing fuses and their co-ordination problems are very similar to those of oil circuit reclosers. Heating and cooling periods of the back-up fuse must be considered in both cases. Proper consideration of the heating and cooling effect on fuses has presented one of the larger intangible problems in distribution co-ordination in recent years. The authors have considered this problem and mention that it will be the subject of a future paper. It is hoped this paper will present a simple method to take the heating and cooling period of fuses into consideration and that the method will be applicable to fuses and oil circuit reclosers of all manufacturers.

It is to be noted from Figure 6 of the paper when consideration is given to all the co-ordination factors, a rather small space is open for applying a line-side fuse. Short-circuit currents often occurring on line-side fuses cover a large portion of the interrupting range of reclosers. From inspection of Figure 6, it may be seen co-ordination would not always be possible. A faster instantaneous operation and a time-delay curve more nearly approaching the slope of a fuse curve would aid the solution of this problem.

Inrush current from mine motors is given as an explanation for the 1-cycle operation of the instantaneous operation of the recloser in the oscillogram shown in Figure 11. It seems a little unreasonable that under proper application where a recloser size is chosen to allow for future load growth, inrush current from motors would cause the fast operation pictured. Many motors have undervoltage controls that remove them from the line on loss of potential. In 40 cycles, the inertia of most motors, large and small, would be of such value that only partial reduction of speed should occur. This would substantially reduce the inrush current that would be present if locked rotor conditions existed. Field checks of several different types of oil circuit reclosers, including the *FR-1*, have revealed the instantaneous shots do not always conform to the published curve and are often faster.

Our field tests would indicate the 1-cycle operation is more likely the result of oil circuit recloser timing inaccuracies rather than motor inrush current. It would have been interesting to have observed one or two more tests performed under the conditions stated for Figure 11. It is agreed that, in any event, proper co-ordination will still be obtained.

The co-ordinated application of reclosers with fuses has been somewhat haphazard in the past. Operation engineers are realizing the need for analytical co-ordination studies before the applications of reclosers are made. For the application engineer this paper should provide a good summary of present-day recloser co-ordination methods.

S. R. Smith, Jr. (General Electric Company, Pittsfield, Mass.): Referring to the section on Cooling of the Fuse Link During Intervals That the Recloser is Open of the author's paper, the additional increment which is added to the fuse curves to factor fuse cooling during the open intervals of the recloser is

$$\frac{I_{300}^2}{i^2}\,T_d$$

where

I_{300} = 300-second current value from the fuse curve being used (or where the curve is asymptotic with the time axis)

T_d = total time the recloser is open for the operating cycle involved

i = circuit current.

To further explain the method of using this cooling correction, consider first the case where it is desired that the recloser go through a given sequence of operations without partial melting of a particular fuse. To ascertain the limit of co-ordination we start with the published fuse melting time curve and add $(I_{300}^2/i^2)\,T_d$ to points along the curve, simultaneously subtracting 25 per cent of the melting time to allow for operating variables (as explained in the paper) so as to arrive at a corrected fuse melting curve. This curve is superimposed on the curve of total opening time of the recloser for the sequence involved (sum of all instantaneous, or instantaneous plus time-delay opening times as determined from the published recloser curves). The point where these curves intersect indicates the current limit to which recloser will function without partially melting the fuse.

Conversely, for the case where the fuse is to clear the circuit before the recloser goes through a given operating sequence, we start with the published fuse total clearing time curve and add $(I_{300}^2/i^2)\,T_d$ to points along the curve so as to arrive at a corrected fuse clearing time curve (conservatism dictates omission of the minus 25 per cent factor for operating variables in this case). This curve is superimposed on the curve of total opening time of the recloser for the sequence involved (sum of all instantaneous, or instantaneous plus time-delay opening times as determined from the published recloser curves). The point where these curves intersect indicates the current limit to which fuse will clear before recloser completes its sequence of operations.

Study of the foregoing methods will show that the same results can be achieved by changing the sign of the corrections and applying them to the recloser curve instead of to the fuse curve.

The cooling correction given before derives from the fuse heat balance equations and we have used it for a number of years in applying reclosing fuses. The point of caution is on very fast fuses, for example where the 0.1-second melting current is only five times the 300-second melting current, in which case the correction may be too large if the individual reclosing intervals are longer than approximately 1.5 seconds.

Chase Hutchinson (Ebasco Services, Incorporated, New York, N. Y.): The benefits of selective operation between circuit breakers or reclosers and fuses has become recognized generally throughout the industry. On overhead distribution lines these benefits are usually manifest by improved service continuity and reduced operating cost. Maximum benefits from a given sequence of operations can be secured by use of accurate application procedures for devices having definite and known operating characteristics. Thus the application procedure described by the authors and checked by field tests should be helpful in obtaining a closer approach to perfect operation of reclosers.

When a fuse is exposed to fault current the heat input is I^2Kt where t is time. For several pulses of fault current of equal magnitude the heat input is

$$I^2K(t_1+t_2+t_3\ldots tn)$$

If no cooling occurs between the several pulses or if the amount of cooling is small the accumulated heat in the fuse may be taken as the heat produced by I amperes flowing for

$$T=(t_1+t_2+t_3\ldots tn) \text{ seconds}$$

The oscillogram of Figure 4 of the paper seems to bear out this reasoning in that (2.5 + 2.5 + 8.5) = 13.5 cycles was required to blow the fuse which apparently checks the 13.2 cycle value given by the authors as published clearing time.

From this reasoning and the test results it appears for practical applications involving a complete cycle of operations occurring in about two seconds, cooling of the fuse link is a negligible factor while heating of the link is substantially the sum of the several pulses of heat. Unfortunately the authors do not expand this point nor do they describe their method of estimating cooling of the link.

The tests on several reclosers in series are interesting and indicate that a degree of co-ordination is obtained. Perfect co-ordination would, for the sequence used, involve three or four recloser operations as contrasted to the eight recloser operations required to isolate the trouble. In the Figure 12 case the line section between the 25- and 15-ampere recloser was interrupted twice and the line section between the 15-ampere recloser and the 10-ampere recloser was interrupted four times. None of these interruptions were essential to the success of the scheme, but were by-products of the inability of the recloser control mechanism to properly determine fault location. This almost complete lack of co-ordination between instantaneous elements of the several reclosers is a characteristic which the writer feels should receive greater attention in future design.

Leonard M. Olmsted (Duquesne Light Company, Pittsburgh, Pa.): The authors have made a commendable effort to evaluate co-ordination between fuses and oil circuit reclosers, giving consideration to the effect of the fuses cooling partially during the open time of the reclosers. It is interesting to see, however, how much error is introduced if this correction is neglected and the time to melt the fuse taken as a summation of the times during each closed period. Taking the first 370-ampere case, the authors report 2.5 cycles during the first opening of the recloser, 2.5 cycles during the second opening of the recloser, and the fuse blowing in 8.5 cycles during the first time delay period of the recloser. If we add these three, we have a total of 13.5 cycles at 370 amperes to blow the 50-ampere fuse, which compares very favorably with its published time of 13.2 cycles. For this case, then, correction of the fuse curve to allow for cooling time does not appear essential. Applying similar reasoning to the case of the 51-ampere fuse which is intended to blow between the first and second time delay operations of the recloser, Figure 6 of the paper indicates that the fuse requires approximately 28 cycles at 370 amperes to clear. If we deduct from this value the two instantaneous openings at 2 cycles each and the first time delay operation in 19.5 cycles, a total of 23.5 cycles, we would expect the fuse to clear during the second time delay operation in approximately 4.5 cycles. The authors' tests show clearing in 17.5 cycles of the second time delay operation, which is longer than the predicted time but still gives the predicted co-ordination. From these two cases, it would seem reasonable to conclude that correction for cooling time in the fuse link may be desirable but that the error introduced by neglecting it should not be of great importance.

In discussing oil circuit reclosers, it should be kept clearly in mind that the requirements are distinctly different from those applying to most other types of switchgear. Whereas station-type switchgear is installed permanently and with protective characteristics more or less matched to the circuit as a whole, it must be anticipated that pole-mounted reclosers will be subject to frequent relocation as the requirements of the distribution circuits change. Co-ordination with only a single fuse size is not enough. They must cover a wide range of sizes determined by the transformer sizes required for service in some instances to only one residential customer, in other locations for schools, stores, shopping districts, and other sizable consumers. For such applications, it is still desirable that the instantaneous tripping of the recloser be fast enough to protect the smallest fuse link, and that the accumulated time before lockout be sufficient to blow the largest fuse link.

Most of the present reclosers have been designed with a view to application on rural circuits at 7,200 volts or more, where transformer fuses are small and short-circuit currents, limited. When they are installed on suburban circuits operating at 2,400 or 4,160 volts, the relationship between the recloser characteristics and the transformer fuse sizes becomes closer. Suburban service requirements are rigid, in many cases indicating the need for automatic sectionalizing equipment, but most of the reclosers now available only partially meet the requirements. The authors appear to have recognized this situation in their proposal that the recloser lock closed on its final operation, thereby throwing the final clearing of a fault on a line fuse which can be of whatever size is required for co-ordination in the circuit.

This feature seems to be distinctly different from previous thought on the matter, but it is my opinion that it is only a compromise until the designers find a way to incorporate sufficient time delay in the recloser mechanism itself. Considerable improvement has been accomplished during the past ten years in this type of equipment, and it is hoped that this improvement will continue until reclosers become available which fully meet all the requirements of suburban distribution.

G. G. Auer, R. A. Branflick, L. J. Woodward, and W. C. McKinley: The discussions of Mr. Olmsted, Mr. Hutchinson, and Mr. Gmeiner confirm the authors' opinion that maximum benefits in co-ordination can be expected when heating and cooling of fuse links is considered during recloser operation. There is general agreement that the heating factor is predominant while the cooling factor is not of too great importance to achieve co-ordination.

Mr. Gmeiner pointed out that by the necessity of adding the required correction factors, limitations were imposed on the application of line-side fuses. This limitation is determined by the characteristics of the overcurrent device on the source side. If this device is an overcurrent relay, the current tap setting based upon short circuit current values rather than load currents will provide room for co-ordination.

It also was pointed out that the instantaneous operations of the reclosers did not conform to the published curves. The published instantaneous curve only indicates the maximum time required for opening of the recloser. A unit might operate in accordance with this curve but, as tests have shown, they usually open faster than indicated. In a co-ordination study or fuse–recloser curve comparison, it is the maximum time in which recloser instantaneous operation can be expected that determines co-ordination possibilities. Faster time of operation is a definite assurance that co-ordination between fuse and recloser will be obtained.

Mr. Chase Hutchinson's thoughts on future design of reclosers which would provide co-ordination during instantaneous operation would be a big improvement from the standpoint of service continuity and elimination of momentary outages on the main line due to branch circuit faults, but to accomplish this, some sacrifice would have to be made in temporary fault protection on the main circuit or else expensive auxiliary equipment would have to be employed.

Mr. S. R. Smith's discussion of the formula to calculate the cooling increment of the fuse link was a great contribution to this paper and did furnish the necessary information to make the analytical procedure complete. Omission of the mathematical procedure and significance of the cooling factor was pointed out by Mr. Gmeiner, Mr. Hutchinson, and Mr. Olmsted.

Wide-Band D-C Amplifier Stabilized for Gain and for Zero

A. J. WILLIAMS, Jr.

WILL McADAM
ASSOCIATE AIEE

Synopsis: Previous technical literature has described direct-coupled d-c amplifiers having a wide frequency pass band but with appreciable zero drift,[1,2] and also has described contact-modulated d-c amplifiers having a relatively stable zero but with a narrow pass band.[3] This paper describes an arrangement of a direct-coupled amplifier together with a contact-modulated amplifier. This arrangement retains the wide band of the former and the zero stability of the latter. Block diagrams are used for explanation, and schematic circuits are given for an experimental setup. Records from a fast recorder and from an oscillograph disclose the results achieved, such as rapid response to a step input and greatly reduced, nonpermanent output disturbances following large, unbalanced changes of heater voltage.

ALMOST any electron tube is fundamentally a d-c amplifier having a wide pass band but, in practice, when it is used simply as a "direct-coupled" d-c amplifier, precautions must be taken to retain stability in the face of changes in supply voltage, cathode temperature, cathode emission characteristics, and contact potentials of the tube electrodes, especially of the control grid.[1,2]

A sufficiently stable gain generally can be obtained by the use of negative feedback.[4]

A sufficiently stable zero (zero output for zero input) is more difficult to obtain, some of the precautions being:

1. Stabilized *B* supply for anodes, screens, and so forth.[5]
2. Balanced, bridge, or push-pull arrangement of tubes.[6,7]
3. Stabilized heater (or filament) supply.[5]
4. Adjustable compensation for changes in supply voltage (or for changes in thermionic emission).[8–18]

Because of these zero-stability difficulties with direct-coupled d-c amplifiers, contact-modulated d-c amplifiers have been found useful, first in systems using a mechanical link in the feed-back loop,[19–22] subsequently without a mechanical link and without feedback,[23,24] and eventually without a mechanical link but with feedback (to stabilize gain).[3] The contact-modulated d-c amplifier is useful because its zero is stable to a fraction of a microvolt.[3] Unfortunately, its frequency pass band is limited by the modulation frequency, for instance, with 60 cycle per second modulation and with gain stabilized to about one part in 1,000, the pass band is only about one cycle per second.

This one cycle per second band width (approximately one second response time) applies equally well to the system with the mechanical link (the self-balancing recorder) and to the system without the mechanical link (the contact-modulate d-c amplifier).

Figure 1 shows that the recorder responds completely in less than one second to a step change in input.[22] With the contact-modulated d-c amplifier (narrow-band)[3] ahead of the recorder, the amplifier response time together with the response time of the recorder results in an over-all response time somewhat greater than a second.

The third curve of Figure 1 was taken with the wide-band amplifier which is the subject of this paper. The response time for the third curve is again less than a second, and is essentially the same as for the recorder alone; hence, the amplifier response time is indicated to be small compared with a second. Figure 2 shows a cathode-ray oscillogram of the response of the wide-band zero-stabilized amplifier alone. Since the time markers at the bottom are spaced by 0.01 second, the reponse time can be conservatively stated as less than 0.005 second. In round numbers, therefore, the response time has been reduced by a factor of 200; hence, the band width has been increased by a factor of 200. At this point it should be stated that the particular amplifier used for these tests is only experimental and is not comparable in gain with the more conventional narrow-band amplifier.[3] The

principle, however, appears to be applicable to amplifiers of high gain, working down to the natural limits of noise. The discussion which follows is an attempt to explain that principle.

The Problem and the Principle Used for Its Solution

In a simple direct-coupled d-c amplifier, the presence of zero drift cannot be detected (and hence cannot be corrected for) readily without temporarily taking the amplifier out of service, as by shorting the input and observing the output.[25] However, in a direct-coupled amplifier with gain stabilized to a considerable degree (as by feedback), a comparison of input with output divided by gain tells of the presence of zero disturbance at any and all times, with or without signal. The zero stabilization is made on the basis of this comparison.

Figure 3 gives in block form a conventional direct-coupled amplifier with gain stabilized by feedback. The zero drift or disturbance is symbolized by an equivalent voltage e_d entering in an additive way, symbolized by the small block Σ_2. e_x is the input, and e_o is the output. μ is the forward gain, and β is the attenuation in the feed-back circuit. We may write for this circuit

$$\text{Input} = \text{feedback} + \text{error} \tag{1}$$

$$e_x = e_f + e_r \tag{2}$$

$$e_x = e_o\beta + e_r \tag{3}$$

$$e_x = e_o\beta + e_i - ed \tag{4}$$

$$e_x = e_o\beta + e_o/\mu - ed \tag{5}$$

The performance is most apparent when referred to the input, as indicated by equations 1, 2, 3, 4, and 5. The two right-hand terms in equation 5 are the error terms. e_o/μ is the result of limited forward gain and can be reduced below any assigned quantity by increasing the forward gain, μ. The term $-e_d$ represents the troublesome zero disturbance, the effect of which cannot be reduced by increasing the forward gain.

Figure 3 and equation 3 show that the error e_r, which comes from the summing circuit Σ_1, is the result of comparison of input, e_x, with output divided by gain, $e_o\beta$. The error e_r, therefore, should be used to correct for the zero disturbance, as shown in Figure 4.

It is futile to attempt to detect this error with another direct-coupled d-c amplifier (itself subject to zero disturbance), but a contact-modulated d-c amplifier is well suited to this service because of its freedom from zero disturbance. As shown in Figure 4, such an amplifier is employed and is followed by an integrator whose output may be injected at any convenient point, to the right or to the left of the injection of e_d, but, of course, not to the left of the "take off" for the contact-modulated amplifier. Thus, the action will be the same for a zero disturbance occurring at any point between the take off for the contact-moduated amplifier and the output. For the circuit of Figure 4 we may write

$$e_r = e_x - e_f \tag{6}$$

$$= e_x - e_o\beta \tag{7}$$

$$= e_x - e_i\mu\beta = e_x - (e_r + e_d + e_g)\mu\beta = e_x - (e_r + e_d + \alpha \textstyle\int e_r dt)\mu\beta \tag{8}$$

$$= e_x - e_r\mu\beta - e_d\mu\beta - \mu\beta\alpha \textstyle\int e_r dt \tag{9}$$

$$e_r + \mu\beta e_r + \mu\beta\alpha \textstyle\int e_r dt = e_x - \mu\beta e_d \tag{10}$$

For Figure 4 equations 6, 7, 8, 9, and 10 are developed about the error e_r, since it is the error and its reduction with which we are concerned. Equation 10 gives a clue to the performance because of the presence of the integral term, $\mu\beta\alpha\int e_r\, dt$. The nature of this term and the simplicity of the other terms suggest that the error cannot be very large for very long.

Theoretical Performance

Equation 10 provides a basis for computation of the theoretical performance corresponding to prescribed time forms of e_x and e_d.

For convenient manipulation, equation 10 may be rewritten as

$$e_r + K\alpha \int_0^t e_r dt = \frac{K}{\mu\beta} e_x - Ke_d \tag{11}$$

where e_r, e_x, and e_d are functions of time, t, and are assumed to have zero value for all times prior to the reference time $t = 0$; K is equal to $\mu\beta/(1+\mu\beta)$ and μ, β, and α are constants of the system. The Laplace transform of equation 11 then may be written

$$E_r + K\alpha\frac{E_r}{s} = \frac{K}{\mu\beta} E_x - KE_d \tag{12}$$

where E_r, E_x, and E_d are the Laplace transforms of e_r, e_x, and e_c respectively, as functions of the complex variable, s. Solving this equation for the error voltage

$$E_r = \frac{K}{\mu\beta}\left(\frac{s}{s+K\alpha}\right)E_x - K\left(\frac{s}{s+K\alpha}\right)E_d \tag{13}$$

As one of the interesting prescribed time forms, let e_x and e_d be step functions having values of zero, for t less than zero, and constant values $|e_x|$ and $|e_d|$ respectively for t equal to or greater than zero. The Laplace transforms of e_x and e_d are then

$$E_x = \frac{|e_x|}{s}$$

and

$$E_d = \frac{|e_d|}{s} \tag{14}$$

respectively, and equation 13 becomes

$$E_r=\frac{K}{\mu\beta}|e_x|\left(\frac{1}{s+K\alpha}\right)-K|e_d|\left(\frac{1}{s+K\alpha}\right) \quad (15)$$

Returning now to the time plane

$$e_r=\frac{K}{\mu\beta}|e_x|\epsilon^{-K\alpha t}K-|e_d|\epsilon^{-K\alpha t} \quad (16)$$

Since the principle of this amplifier is based on the product $\mu\beta$ being large compared with unity, K is nearly equal to unity, and a convenient approximation of equation 16 may be written as

$$e_r=\frac{|e_x|}{\mu\beta}\epsilon^{-\alpha t}-|e_d|\epsilon^{-\alpha t} \quad (17)$$

From equation 16, and more readily from equation 17, it can be seen that the error resulting from an abrupt change of signal is small compared with the signal. Initially it is neither greater nor less than that without the zero stabilizing components; it does, however, vanish with time as a result of the stabilizing components. Again from equation 16, and more readily from equation 17, it can be seen that the error resulting from an abrupt application of a zero disturbance is initially equal to the zero disturbance. If zero disturbances of this abrupt nature were common in practice, the stabilizing components would be of little value, even though the effect of a single such disturbance ultimately would vanish. Fortunately, the more common forms of zero disturbance develop slowly, and the stabilizing components are effective. This can be seen from analysis of the response to uniformly changing or "ramp" functions for e_x and e_d.

In this case, e_x and e_d have values of zero for t less than zero, and values expressed by

$$e_x=a_xt$$

and

$$e_d=a_dt \quad (18)$$

for t equal to, or greater than, zero. The Laplace transforms of e_x and e_d are

$$E_x=\frac{a_x}{s^2}$$

and

$$E_d=\frac{a_d}{s^2} \quad (19)$$

respectively, and equation 13 becomes

$$E_r=\frac{K}{\mu\beta}a_x\frac{1}{s(s+K\alpha)}-Ka_d\frac{1}{s(s+K\alpha)} \quad (20)$$

Returning to the time plane

$$e_r=\frac{K}{\mu\beta}\frac{a_x}{\alpha}\left(1-\epsilon^{-K\alpha t}\right)-K\frac{a_d}{\alpha}\left(1-\epsilon^{-K\alpha t}\right) \quad (21)$$

Since K is nearly equal to unity (as before), a convenient approximation for equation 21 is

$$e_r=\frac{1}{\mu\beta}\frac{a_x}{\alpha}\left(1-\epsilon^{-\alpha t}\right)-\frac{a_d}{\alpha}\left(1-\epsilon^{-\alpha t}\right) \quad (22)$$

From equation 21, and more readily from equation 22, it can be seen that the error resulting from a uniformly changing or ramp-type signal is, at all times, quite small.

Again, from equation 21 and more readily from equation 22, if a ramp-type zero disturbance has a rate of rise a_d which is small compared with the integrator coefficient α, its contribution to the error will, at all times, be small.

Experimental Apparatus

An experimental setup was assembled from two items which were on hand:

1. A contact-modulated d-c amplifier[3]
2. A direct-coupled d-c amplifier

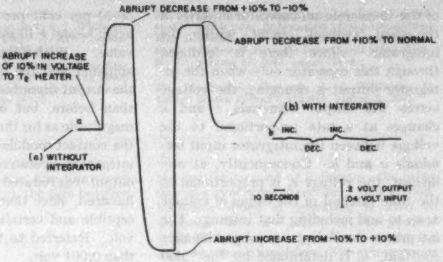

Figure 6. Response to abrupt changes in one heater voltage

The one heater is that of 1/2 of the input stage of the direct-coupled amplifier

Figure 5 shows the direct-coupled voltage amplifier in tube sections T_1, T_2, T_3, T_4, and T_5. The rectifier-filter elements, (which are not shown), supply about 400 direct volts across the B+ and B− terminals.

The principal negative feedback is from the point p through the 5-to-1 voltage divider p-h-g, through the low impedance output of the integrator to the control grid of T_2. More exactly, the feedback is from both terminals of the output load, using both voltage dividers to the two grids of the differential input stage comprising T_1 and T_2. T_1 and T_2 are direct-coupled to T_4 and T_3 respectively to provide effective differential action.

It will be noted that the input signal e_x is connected in series with the grid of T_1 from the divider point d as shown. The integrator output, on the other hand, is connected in series with the grid of T_2 from the other divider point h. Since the voltage dividers p-h-g and b-d-g have exactly the same ratios, the output load voltage bears the proper relation to the input signal (that is, $e_o=e_x/\beta$) only if points a and h are at the same potential. The integrator input terminals are connected to points a and h to measure the error voltage, $e_r=e_x-e_o\beta$, and to effect corrective action by modifying grid potential of T_2 in proper amount, $e_g=\alpha\int e_r dt$, between the integrator output terminals h and c. Since the corrective action is applied to the grid of T_2 rather than the grid of T_1, point c must become negative with respect to point h whenever point a tends to become positive with respect to point h.

The integrating amplifier is the contact-modulated amplifier described in a previous paper,[3] and modified as shown. The principal modification is the insertion of the 12-microfarad capacitor in series in the local feedback circuit, within the integrator. Since there is feedback through this capacitor only when the integrator output is changing, the voltage across the output terminals *c* and *h* changes at a rate proportional to the voltage between the integrator input terminals *a* and *h*. Consequently, at any instant, the voltage e_g is proportional to the time integral of the values of voltage e_r up to and including that instant. The integrator coefficient or proportionality constant, α, is determined by the 7,000 ohms of resistance in the input filter, and the 12 microfarads of capacitance in the feed-back circuit. The determining relation is $\alpha = 1/RC$, so that

$$\frac{1}{\alpha} = RC = 7{,}000 \times 12 \times 10^{-6} = 0.08 \text{ second}$$

for the integrator shown.

Observed Performance

The experimental setup of Figure 5 was used to obtain the third curve of Figure 1 and the oscillogram of Figure 2.

Since changes of cathode temperature are known to produce zero disturbances, the heater voltage of T_2 was varied abruptly ±10 per cent from the rated value, while that of T_1 was held constant at rated value. Figure 6 shows a record of the output voltage. With the contact-modulated amplifier and the integrator inoperative, the output swung more than 1.6 volts. The effect persisted as long as the heater voltage was held off normal. With the contact-modulated amplifier and the integrator operative, the output voltage swing was only 0.03 volt, or a reduction of 50-to-1; moreover, after about 10 seconds, the output disturbance had vanished.

Figure 7 shows the effect of changing the heater voltage of T_2 at a uniform rate of 20 per cent per minute, the changes again being ±10 per cent from the rated value. With the contact-modulated amplifier and the integrator inoperative, the output disturbance was more gradual than before, but of the same ultimate magnitude as for the abrupt change. With the contact-modulated amplifier and the integrator operative, the effect on the output was reduced by a factor of several hundred, since that effect is barely perceptible and certainly is less than 0.005 volt. Referred to the input, this is less than 0.001 volt.

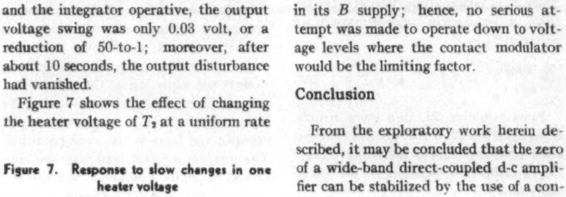

Figure 7. Response to slow changes in one heater voltage

This small order of error is predictable from equation 22. The first curve of Figure 7, with the contact-modulated amplifier and the integrator inoperative, shows the output voltage changing at about 0.04 volt per second, which is 0.008 volt per second when referred to the input. That is, $a_d = 0.008$ volt per second. $1/\alpha$, as determined by the resistance and capacitance constants of the experimental apparatus, was previously calculated as 0.08 second. Extracting from equation 22 the term applicable to the maximum error from a ramp-type zero disturbance

$$e_{r_{max}} = \frac{a_d}{\alpha} = a_d \frac{1}{\alpha}$$

$$= (0.008 \text{ volt per second})\,(0.08 \text{ second})$$

$$\cong 0.0006 \text{ volt}$$

Hence the calculated value of error checks the observed value, in that both are less than 0.001 volt.

The direct-coupled amplifier with which this experimental work was done had definite limitations, such as fluctuations in its *B* supply; hence, no serious attempt was made to operate down to voltage levels where the contact modulator would be the limiting factor.

Conclusion

From the exploratory work herein described, it may be concluded that the zero of a wide-band direct-coupled d-c amplifier can be stabilized by the use of a contact modulator without reduction of the over-all frequency pass band, which is limited by the response characteristics of the direct-coupled amplifier alone, and which is independent of the modulation frequency.

Discussion

Edwin A. Goldberg (RCA Laboratories, Princeton, New Jersey): The principle of the wide-band zero-stabilized amplifier disclosed by Mr. Williams has been employed for quite some time in amplifiers developed under a government contract at the RCA Laboratories for the Special Devices Center, Office of Naval Research for computing purposes. This development was declassified on June 15, 1949. It is also used by the Reeves Instrument Company in amplifiers employed in some models of the *REAC* analog computer. Figure 1 of the discussion is a block diagram of the version used. It utilizes current-summation feedback rather than voltage-summation feedback, and provides for both a grounded input and grounded output without utilizing any floating power sources. The d-c amplifier portion is quite conventional. A is the input grid terminal of the first tube, B is the amplifier output terminal, and C is a point within the amplifier where a zero setting voltage normally is applied. Z_f is the feedback impedance, and Z_i the input impedance. A sample of the voltage at A is chopped, amplified by an a-c amplifier, rectified by a synchronous rectifier, filtered, and applied to point C. If the d-c amplifier has the same gain, $G_1(\omega)$, for signals applied at either point A or point C, and the gain of the chopper, amplifier, rectifier, and filter from point A to point C is $G_2(\omega)$, the gain between points A and B is

$$G_{AB}(\omega)=G_1(\omega)G_2(\omega)+G_1(\omega)$$

At d-c ($\omega=0$), $G_1(0)=50{,}000$ and $G_2(0)=3{,}000$ giving a value for the forward gain $G_{AB}(0)$ of 150×10^6 in a typical computing amplifier, and making possible very high feed-back loop gain to stabilize net over-all gain with feedback against variations in gain within the amplifier itself.

As the frequency increases from direct current, $G_2(\omega)$ decreases about six decibels per octave due to the time constant of 10 seconds for the filter. At 50 cycles, the $G_2(\omega)$ is about unity while $G_1(\omega)$ is still about 50,000, resulting in a forward gain of 100,000. Thus, it can be seen that in addition to minimizing zero offset and drift, the stabilizer also increases the net forward gain even for low a-c frequencies. At high frequencies, $G_2(\omega)$ becomes negligible, and the forward gain is the same as the gain of the d-c amplifier without the stabilizer. The tube complement of this amplifier consists of a *5692*, a *6SH7*, and a *6V6* in the d-c amplifier, and two *5693*'s in the a-c amplifier.

The mechanical chopper is an unpolarized vibrating-reed device which is driven from a 193-cycle source and vibrates at 386 cycles. It has two pairs of contacts, one pair being used as a chopper, the other pair as a synchronous rectifier. The second-harmonic mode of operation is used to minimize false d-c offset due to possible stray 193-cycle pickup from the vibrator drive in the a-c amplifier. The synchronous rectifier is insensitive to frequencies other than 386 cycles.

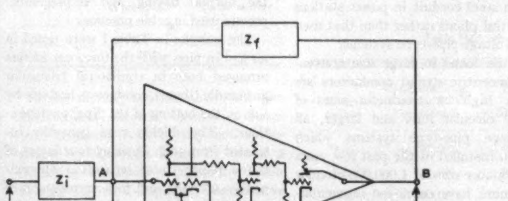

Figure 1. Block diagram of wide-band amplifier

The gain of the amplifier with feedback is the ratio Z_f/Z_i. If Z_f and Z_i are both resistors, the amplifier has a flat frequency response. By supplying several inputs through separate resistors, the amplifier becomes an adding device. If Z_f is made a capacitor and Z_i a resistor, the device becomes an integrator which has an extremely low inherent drift rate. If Z_i is made a capacitor and Z_f a resistor, the device becomes an excellent differentiator with a negligible d-c offset.

The magnitude of d-c offset referred to input grid of the stabilized amplifier depends on three factors:

1. **The inherent effective d-c offset of the chopper itself and associated circuits**
2. **The value of $G_2(0)$**
3. **The voltage e_d which would normally have to be applied at C to zero the amplifier.**

The offset due to (1) is normally negligible, provided the chopper is carefully made and utilized. The offset due to (2) and (3) to first order approximation is $e_d/G_2(0)$. Offsets of about 50 microvolts or less may be obtained fairly easily in computing amplifiers utilizing input and feed-back resistors in the megohm range.

This principle of zero drift elimination may be applied to extremely broad band amplifiers such as video amplifiers with flat response from direct current to extremely high frequencies. The response characteristics of the computing amplifiers used by RCA Laboratories depends on the nature of Z_f and Z_i; however, if both Z_f and Z_i are resistors, the response is extremely flat from direct current to 100 kc.

The accuracy, utility, and ease of operation of d-c-type analog computers have been increased by a large factor through the incorporation of these amplifiers, because the frequent manual adjustments of the amplifier d-c zeros have been eliminated entirely.

A. J. Williams, Jr.: It is gratifying to learn from Mr. Goldberg that he and others have found utility in a wide-band zero-stabilized amplifier similar in principle to the amplifier we have described. Over 20 years of experience with chopper amplifiers at Leeds and Northrup Company have given us considerable confidence in them; hence we are inclined to think up new ways to use them and are pleased that others find new ways to use them too.

A-C Resistance of Segmental Cables in Steel Pipe

L. MEYERHOFF
MEMBER AIEE

G. S. EAGER, JR.
ASSOCIATE AIEE

Synopsis: In recent years, there has been a very great increase in the use of pipe-type systems for long, high-voltage impregnated-paper transmission feeders. Thus, a detailed knowledge of the factors influencing the a-c losses of large size conductors with relatively low skin-proximity effect characteristics is of value to all cable and operating engineers. This paper reports the results of a study of the effective a-c resistance of a compact type of segmental conductor in sizes from 1,000,000 to 2,000,000 circular mils, in air and in steel pipe, with equilateral triangular and cradle configurations. From analysis of the data, an approximate separation is made of losses occurring in the conductor, the outer shield structure and the steel pipe. These component losses are compared with accepted and derived formulas, and application of the data is thus broadened by use of mathematical methods. Based upon the suggested methods of computation, tables are given of losses of cables in steel pipe over a range of conductor sizes and voltage ratings.

SINCE the war there has been a great increase in the use of impregnated paper insulation under high oil or gas-pressure in steel pipe for long high-voltage transmission feeders. Thus, the need for reliable data on carrying capacities of such systems has been greatly enhanced.

The data here presented are not claimed or believed to constitute a complete answer to the problem and are submitted with the hope that they will be found useful to the industry and serve to stimulate other investigators in the accumulation of further data. In presenting this paper, the authors do so with a full appreciation of the benefits accruing to the entire industry from a free discussion of the design factors involved. Sufficient operating and test data have not been and are not available to justify the making of warranties.

While considerable data on the purely thermal elements of the problem have been given in a previous publication[10] only very meager data are available in the technical literature on the a-c loss aspect of cable assemblies of practical interest in pipe-type systems.

Wiseman[1] has made available to the industry data on conventional concentric strand conductors in steel pipe, and also has presented measurements on a single size of segmental conductor. However, in all cases the cable assembly employed was designed primarily to simulate that used in practice on nonleaded low-voltage rubber or varnished cambric cables installed in steel conduit in power stations or industrial plants rather than that used on high-voltage pipe-type systems.

Since the losses in large size conventional concentric strand conductors are relatively high for conductor sizes of 1,000,000 circular mils and larger, all high-voltage pipe-type systems which have been installed in the past few years with conductor sizes of 1,000,000 circular mils or more have employed segmental-type conductors to obtain lower a-c losses.

In the construction of high-voltage pipe-type cables it has been the invariable practice to provide mechanical protection over the individual cables in the form of helically applied, D-shaped copper wires, sometimes termed skid wires. These are usually applied over a surface wrapping consisting of one or more copper tapes intercalated with nonconducting tapes. In some constructions, the nonconducting tape has been a heavy cotton, duck, or paper tape. In others, a polyethylene tape has been used because of its nonhygroscopic nature. In some cable which has been manufactured the surface wrapping has been comprised of two intercalated copper tapes. (None of these cables had a permanent lead sheath.) The protective covering just described, which will be termed the "shield" in what follows, contributes a significant fraction of the total a-c loss of the system, largely because of the circulating currents set up by the induced voltage.

Cables Tested

The cable samples tested and their construction were those shown in Table I. All conductors consisted of four segments, three of which were insulated (insulation consisted of three paper tapes), bound together by a slightly overlapped bronze tape of about 40 per cent conductivity. The individual 90-degree segments were of the Compack type, the essential characteristic of which is that all layers are stranded in one direction, each layer being rolled as applied. In all cases the cable samples were subjected to the normal drying and impregnating process used in cable practice.

The samples in Table I were tested in air and in pipe, with the three conductors arranged both in equilateral triangular and cradle (that is, conductors laid side by side on the bottom of the pipe) configurations. The shields were generally insulated from each other by four layers of heavy paper (total separation approximately 40 mils) and measurements were made both with the shields electrically connected together at the ends, and with the shields not connected together.

For samples *1A*, *1B*, *3A* and *3B*, the pipe used was a length of electrically-welded steel pipe 20 feet 6 inches long having an internal diameter of 6.10 inches and a wall thickness of 0.28 inch and having electrical characteristics as shown in Table II. The cable lengths

used were 25 feet, potential points being placed 20 feet apart.

For samples *2A* and *2B*, the pipe used was a length of lap-welded steel pipe 15 feet 6 inches long having an internal diameter of 8.02 inches and a wall thickness of 0.32 inch and having electrical characteristics as shown in Table II. The cable lengths used were 20 feet, potential points being placed 15 feet apart.

Copper lugs were soldered to each end of each cable length. At each potential point the insulation, the outer shield, the binder, and the segment insulation were removed for a longitudinal distance of one inch. Potential leads were soldered to the conductor, and the segments tied together at the potential points by binding wire.

Measurements—Methods and Accuracy

The apparatus and methods of measurement are described in detail in Appendix I. This Appendix also discusses the accuracy of the resistance measurements and gives results of comparative tests with other laboratories or equipment.

Cable 3A, together with the 6-inch pipe used in the present series of measurements was sent to the Electrical Testing Laboratories (ETL) for comparative measurements. A-c to d-c ratios compared as follows:

	Cable in Air	Cable in Pipe
Authors	1.19	1.63
ETL	1.205	1.65

While making a joint study with the Philadelphia Electric Company, losses were measured both by the method described in Appendix I and by use of a deflecting wattmeter supplied by Philadelphia Electric Company. Comparative values of watts loss were as follows:

	At Room Temperature	At 68.5 Degrees Centigrade
Authors	714	732
Philadelphia Electric Company	713	736

These comparisons are described in greater detail in Appendix I.

Results of Experimental Work

Measurements were made for each size and configuration of cable, at five currents—160, 320, 480, 640 and 800 amperes. Temperatures during the measurements were in the range of 26 to 32 degrees centigrade. The results reported in the following tables, unless otherwise noted, are at ambient temperature somewhere in this range, and at a conductor current of 800 amperes for 1,500,000 and 2,000,000-circular-mil conductor sizes, and 640 amperes for the smaller sizes.

Single-Phase Measurements—Skin Effect

In Table III are listed measured skin effect values of the various cables tested, in comparison with values computed on the basis that the skin effect of a segmental conductor is equal to that of a round conductor having 2.3 times the d-c resistance of the segmental.

THREE-PHASE MEASUREMENTS—IN AIR AND IN PIPE

Measured loss ratios for triangular configuration in air are given in Table IV; for triangular configuration in steel pipe in Table V; and for cradle configuration in steel pipe in Table VI. In each table there are shown for comparison values computed as later explained.

CALORIMETRIC MEASUREMENTS OF PIPE LOSS (Y_t)

Five calorimetric measurements of pipe loss were made by a method paralleling that used by Salter[2] but with certain refinements to give greater assurance of accuracy. The method used is described in detail in Appendix I. The results of these measurements are shown in Table VII.

Table VII. Pipe Loss (Y_t)—Calorimetric Measurements

** Uninsulated conductors (segmental), assembled with desired spacing and configuration by means of mechanical separators.

† In terms of d-c conductor loss.

INDUCED VOLTAGE IN SHIELD

Induced shield voltage was measured on one type of cable in air and in pipe to establish the ratio between the two. The measured value in air agreed very satisfactorily with the value computed from the equation

$$e = 0.0529\ I\ \log_{10}\frac{S}{c} \qquad (1)$$

where

e = induced voltage, volts to neutral, per 1,000 feet
S = center-to-center spacing of conductors, inches
c = mean shield radius, inches
I = current in amperes

The ratio between the induced voltages in pipe and in air was found to be 1.35 and this value has been used in the computations of shield circulating current. It is interesting to note in this connection, though not directly pertinent, that Del Mar[9] reports a ratio of 1.3 between the reactance of cables in pipe and in air. Results are shown in Table VIII.

SHIELD RESISTANCE

Resistance of some of the shields and components was measured and values obtained as in Table IX. These measured values were used as a basis for calculating the shield and component resistances of the various shields.

Determination of Component Losses from the Data

Measurements having been made in air and in pipe, with shields insulated and with shields short circuited, on cables with low-resistance shields and on similar cables with high-resistance shields, it is possible to arrive by differences at reasonable approximations of the component losses in air and in pipe. For the separation of the losses in pipe it was necessary first to calculate the pipe loss itself, which was done by use of semi-empirical equation 15, with $K_1 = 0.020$ for the 6.10-inch inside diameter pipe and 0.017 for the 8.02-inch inside diameter pipe, determination of which is shown in Table VII.

The results of the separation of losses for the six segmental cables here reported are shown in Table X, together with the method used in arriving at the various values.

Development of Method for Computation of Losses

Based upon accepted equations for computation of the component losses in air, modified formulas have been developed for the computation of corresponding component losses in pipe, the modifications being those indicated by the data. Additionally, a formula for pipe loss in nonmagnetic pipe has been developed and this also has been modified, as indicated by the data, for magnetic pipe.

In a 3-phase system of the type here discussed, with current, I, flowing through the conductors, the a-c loss may be expressed as I^2R_{ac}, where R_{ac} is the effective a-c resistance. R_{ac} may be regarded as consisting of several components and may be expressed for convenience in terms of R_{dc}, the d-c resistance, as

$$\frac{R_{ac}}{R_{dc}}=1+Y_c+Y_s+Y_i \qquad (2)$$

where

Y_c = increment in ratio due to increased losses in the conductor

Y_s = increment in ratio due to losses in the shield

Y_i = increment in ratio due to losses in the pipe

Y_c and Y_s may be further subdivided as follows

$$Y_c=Y_o+Y_{cp} \qquad (3)$$

and

$$Y_s=Y_{sc}+Y_{sp} \qquad (4)$$

where

Y_o = increment in ratio due to skin effect in the conductors

Y_{cp} = increment in ratio due to proximity effect in the conductors

Y_{sc} = increment in ratio due to circulating current in the shield

Y_{sp} = increment in ratio due to proximity effect in the shield

If the system is operated in air instead of in pipe, Y_i vanishes. To avoid confusion, the symbols for component losses in air will be shown, respectively, as Y_c', Y_s', and so forth.

Each of the foregoing components must be evaluated separately, and may be evaluated in the manner given below. It should be noted that absolute accuracy for each component is not claimed, as there is doubtless some influence of each component on each of the others. However, the total loss as calculated fits satisfactorily the total losses determined on the samples actually measured, and there is also fairly satisfactory correlation between calculated component losses and corresponding component losses as measured directly or as derived from measurements. It is believed that the scheme of evaluation here given provides a rational basis for evaluation of losses within the practical range of segmental high-voltage cables in pipe.

Inasmuch as all measurements were made at 26 to 32 degrees centigrade, the values obtained in the below calculations are on the basis of a temperature of 30 degrees centigrade. Later it will be indicated how the results may be translated to other temperatures.

The forms of the equation used in the following are, as far as possible, based on those of equations generally accepted, but the constants are in general obtained empirically on the basis of component losses derived from the data.

CONDUCTOR SKIN EFFECT (Y_o)

Skin effect of segmental conductors may be evaluated reasonably closely by use of the more or less generally accepted rule that it is equal to the skin effect of a round solid conductor having 2.3 times the d-c resistance of the segmental conductor. For convenience, the values for conductors from 1,000,000 to 2,000,000 circular mils are given in Table XI.

CONDUCTOR PROXIMITY EFFECT (Y_{cp} AND Y_{cp}')

The proximity effect, resulting from superposition of the magnetic fields due to the individual currents in the three conductors, has been worked out for round solid conductors by various in-

Y_{sp}' and $Y_{sp} = RSI$ (B sample)—RSI (A sample). Assumed 0 for A sample.

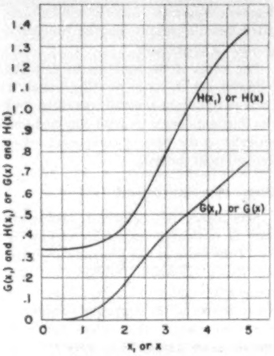

Figure 1. *G* and *H* functions to be used with equation 6 for determination of conductor proximity effect (Y_{cp}')

vestigators and is expressed by the following equation, as given by Arnold[4] for the 3-phase case in air for balanced 3-phase currents, the conductors being in equilateral triangular configuration.

$$Y_{cp}' = \frac{1.5\alpha^2 G(x)}{1-0.208\alpha^2 H(x)} \qquad (5)$$

where

$\alpha = d/S$
d = diameter of the conductor in inches
S = center-to-center spacing of the conductors in inches
$G(x)$ and $H(x)$ are Bessel functions, which are given in the curves of Figure 1
$x = 6.80/\sqrt{R_{dc}}$ at 60 cycles
R_{dc} is the d-c resistance of each conductor in microhms per foot

For segmental conductors Arnold's equation has been modified as follows

$$Y_{cp}' = \frac{1.5\alpha^2 G(x_1)}{1-0.208\alpha^2 H(x_1)} \qquad (6)$$

where all symbols are as in equation 5 and

$x_1 = K/\sqrt{R_{dc}}$

where K is a factor having a value of 3.8 for segmental conductors with three insulated segments, such as used in the cables here reported.

Limited data on other segmental cables, not here reported, indicate that K is influenced considerably by whether or not the conductors were "treated" (that is, had received the drying and saturating treatment usual for impregnated paper cables), by whether two or three of the segments were insulated and by the type of binder holding the segments together.

Table XI. Skin Effect of Segmental Conductors at 30 Degrees Centigrade

Circular Mils	Y_o
1,000,000	0.017
1,250,000	0.026
1,500,000	0.038
1,750,000	0.050
2,000,000	0.065

Based on d-c resistance values as given in Table XVI-A of Reference 3,* adjusted to 30 degrees centigrade. Skin effect = that of round solid conductor having 2.3 times the d-c resistance of the segmental conductor.
* See References at end of paper.

With three segments insulated these variables have little effect. With two segments insulated, however, a K value as high as 6.0 was obtained for an untreated conductor having a bronze binder applied with a slight lap. It may be of interest to note that on the 2,500,000-circular-mil segmental cable, measurements on which were reported by Wiseman,[1] the reported proximity effect in air corresponds to a K value of 5.4. These values compare with a K value of 6.80 for solid conductors.

For $K = 3.8$ proximity effect in air may be obtained from Table XII. For other values of K, equation 6 and Figure 1 may be used.

TOTAL CONDUCTOR LOSS INCREMENT (Y_c AND Y_c')

The total conductor loss increment in air (Y_c') is the sum of Y_o and Y_{cp}'. From all the data on segmental conductors which were available to the authors it appears that the conductor loss increment in pipe (Y_c) bears the following empirical relation to Y'_c

$$\frac{Y_c}{Y_c'} = 1 + \frac{28d(S-d)}{p^2} \qquad (7)$$

The data given by Wiseman[1] for the 2,500,000-circular-mil segmental cable also fit equation 7. This equation also applies with fair accuracy to the data given by Wiseman for concentric conductors in triangular configuration in conduit, but not in steel pipe.

In practical cables Y_c/Y_c' generally will be found to have a value of about two.

With cradle configuration in pipe it is conservative to use the same Y_c value as for triangular configuration.

SHIELD CIRCULATING CURRENT LOSS (Y_{sc} AND Y_{sc}')

A well accepted equation,[7] for the losses in the shield, in air, due to circulating current is

$$Y_{sc}' = \frac{R_s}{R_c}\,\frac{X_s^2}{R_s^2+X_s^2} \qquad (8)$$

where

R_s = longitudinal resistance of the shield including skid wires in microhms per foot
R_c = conductor resistance in microhms per foot
X_s = reactance of the shield in microhms per foot
= 52.9 $\log_{10}(S/c)$ at 60 cycles
c = mean shield radius in inches

For the usual case of cables bunched together and equipped with skid wires, S/c is about 2.20, whose logarithm to base 10 is 0.343, and $X_s = 18.2$.

It may also be noted that X_s for close spacing is small compared to R_s and may be neglected in the denominator. Thus, for close equilateral spacing, equation 8 may be rewritten as

$$Y_{sc}' = \frac{X_s^2}{R_s R_c} = \frac{330}{R_s R_c} \qquad (9)$$

In practical cases the value of R_s is approximately 300 microhms per inch of diameter over the skid wires, per foot of cable, where the shield is of the construction which we have designated as "high resistance" with two 100 by 200 mil copper D-wires applied double start with about 1-inch longitudinal spacing. The value of R_s is approximately one-quarter of the above value where the shield consists of two intercalated 3-mil copper tapes, with skid wires as above.

For equilateral triangular spacing in pipe our data show that X_s is 1.35 times its value in air, see Table VIII. Thus, for equilateral triangular spacing in pipe, equation 9 becomes

$$Y_{sc}=\frac{600}{R_sR_c}\text{ (triangular)}. \tag{10}$$

For cradle configuration, the spacing may be taken as

$$S'=\sqrt[3]{S_1S_2S_3}$$

where S_1, S_2 and S_3 are the respective separations between each pair of conductors.

The ratio of S' to S is in general equal to about 1.16.

Thus

$$Y_{sc}=\frac{850}{R_sR_c}\text{ (cradle)} \tag{10A}$$

However, for low resistance shield it is important to obtain the actual value of S' and evaluate the constant in equation 10(A) directly.

SHIELD PROXIMITY LOSS (Y_{sp} AND Y_{sp}')

The shield proximity loss is due to eddy currents induced in the shield by the main currents. The equation for this loss, based on an equation given by Wedmore,[6] is

$$Y_{sp}'=\frac{398}{R_s'R_c}\left(\frac{c}{S}\right)^2 \tag{11}$$

in which c, S and R_c have the same meaning as in equation 8, and R_s' is the resistance of the shield minus skid wires, in microhms per foot.

For shields in which the copper tapes are intercalated with nonmetallic tapes R_s' is so high (order of 5,000) that Y_{sp} and Y_{sp}' are negligible. For shields in which two copper tapes are intercalated with each other, however, R_s' is only of the order of 300 microhms per foot and Y_{sp}' may be quite large.

Equation 11 may be simplified by substituting in place of c/S its usual value of about 0.46. With this substitution, equation 11 becomes

$$Y_{sp}'=\frac{84}{R_s'R_c}\text{ (triangular)} \tag{12}$$

For triangular configuration in pipe the shield proximity loss Y_{sp} is about 2.5 times Y_{sp}'.

For cradle configuration it may be taken as the same as for triangular configuration.

Thus

$$Y_{sp}=\frac{210}{R_s'R_c}\text{ (triangular or cradle)} \tag{13}$$

PIPE LOSS (Y_t)

An equation for the loss in nonmagnetic pipe, under 3-phase operation, has been derived by one of the authors upon the assumption that the conductor currents may be considered as concentrated at the centers of the conductors and that the various circulating and eddy currents existing in the system do not affect the pipe loss. The derivation of this equation is indicated in Appendix II.

The equation for loss in nonmagnetic pipe, as derived, is

$$Y_t\begin{pmatrix}\text{nonmagnetic}\\ \text{at 60 cycles}\end{pmatrix}=\frac{1.51p't\,(CI)\,Q}{\rho\rho_c} \tag{14}$$

where

p' = mean pipe diameter in inches

t = pipe thickness in inches

(CI) = area of one conductor in circular inches

ρ = resistivity of pipe in microhm-inches

ρ_c = resistivity of conductor in microhm-inches

$$Q=\sum_{n=1}^{\infty}\frac{a^{2n}+b^{2n}+c^{2n}-a^nb^n\cos n\underline{|AB}-b^nc^n\cos n\underline{|BC}-c^na^n\cos n\underline{|CA}}{n^2}$$

$a=2A/p'$; $b=2B/p'$; $c=2C/p'$

A, B, C = distances in inches between the center of the pipe and the respective centers of the three conductors

$\underline{|AB}$, $\underline{|BC}$, $\underline{|CA}$ = the angles formed between the respective lines joining the center of the pipe and the centers of the three conductors

For magnetic pipe it is assumed that the equation can be used with an empirical modification of the term in front of the summation. It has been determined that the following applies for the several cases in which pipe loss was measured with the cables in triangular and cradled configurations.

$$Y_t\begin{pmatrix}\text{magnetic}\\ \text{at 60 cycles}\end{pmatrix}=K_1p(CI)Q \tag{15}$$

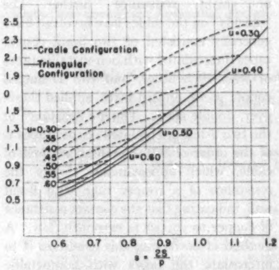

Figure 2. Factor Q to be used with pipe loss equation 16 for triangular and cradle configurations

S = center-to-center conductor spacing in inches

p = inside diameter of pipe in inches

$u=2U/p$ where U = distance between inner pipe surface and center of contiguous conductor in inches

In equation 15 all notations are as in equation 14 except that p' is replaced by p, the inside diameter of the magnetic pipe, and K_1 is a constant depending on the material of the pipe.

K_1 has been determined empirically as 0.020 for the 6-inch pipe used in the measurements, and as 0.017 for the 8-inch pipe, see Table VII. It is recommended in the interest of conservatism that for estimating purposes a value of 0.020 for K_1 be used.

Thus, for estimating purposes equation 15 becomes simply

$$Y_t\begin{pmatrix}\text{magnetic}\\ \text{at 60 cycles}\end{pmatrix}=0.020\,p(CI)Q \tag{16}$$

where

Q = a series having values shown in Table XIII for most practical cases and in Figure 2 for more general application.

Table XIII. Values of Q for Equation 16

$s=\frac{2S}{p}$	Triangular Configuration	Cradle Configuration
0.65	0.78	1.36

0.90	1.32	1.46

EVALUATION FOR TEMPERATURES OTHER THAN 30 DEGREES CENTIGRADE

As stated previously, all the data in the present series were obtained at temperatures in the neighborhood of 30 degrees centigrade. Thus, the ratio of a-c to d-c resistance as evaluated above is at 30 degrees centigrade.

Table XIV gives data for calculation of skin effect of round conductors at 60, 65, 70, and 75 degrees centigrade if the skin effect at 30 degrees centigrade is known. It has been found convenient to use these data for estimation of all a-c losses. Wiseman[1] has found that this method may be used with good accuracy in connection with the data reported by him. One isolated check which we have made indicates that using the table to evaluate the ratio at a higher temperature from the ratio at a lower temperature is conservative. The evaluation may be carried out for the entire loss or for the loss up to any desired point. For example, assume the 30 degree ratios of a-c to d-c resistance to be 1.10 at the conductor, 1.20 at the shield and 1.40 at the pipe. From Table XIV, the ratios at 70 degrees centigrade conductor temperature will be 1.08 at the conductor, 1.16 at the shield and 1.33 at the pipe.

Table XIV. R_{ac}/R_{ac}

BRIEF SUMMARY OF COMPUTATION OF LOSSES

1. Obtain Y_o from Table XI.
2. Obtain Y_{cp}' from Table XII.
3. Add Y_o and Y_{cp}' to obtain Y_c'.
4. Multiply Y_c', by factor from equation 7 to obtain Y_c for both triangular and cradle configurations.
5. Calculate Y_{sc} by equation 10 for triangular configuration, or by equation 10(A) for cradle configuration.
6. Calculate Y_{sp} by equation 13. This is negligible for cable with high-resistance shield.
7. Add Y_{sc} and Y_{sp} to obtain Y_s.
8. Obtain Y_t from Table XIII and equation 16.
9. $1+Y_c+Y_s+Y_t$ = ratio of a-c to d-c resistance at 30 degrees centigrade.
10. Obtain ratio at desired temperature from Table XIV.

Attention is called to the fact that in making computations to compare "computed" loss values with measured values, as shown in Tables IV, V, and VI, the short-cut methods indicated in the equations given in this section were generally not used, but rather the more exact values determined from actual measured dimensions. Thus, the computed values shown in the tables will in some instances be slightly different than would be obtained from the short-cut equations. In all cases the short-cut equations give the more conservative values.

SAMPLE COMPUTATION OF LOSS RATIO

Given a 2,000,000 circular mil segmental in 6.10-inch (inside diameter) pipe, triangular configuration, $d=1.58$, $p=6.10$, $S=2.42$, $s=2S/p=0.794$, $R_c=5.5$, $R_s=890$.

From Table XI, $Y_o=0.065$. From Table XII, $Y_{cp}=0.064$, and, combining $Y_c'=Y_o+Y_{cp}'=0.129$. From equation 7, $Y_c/Y_c'=1+[(28\times1.58\times0.84)/37.2]=2.00$. Therefore $Y_c=2.00\times0.13=0.26$.

From equation 10, $Y_{sc}=600/(890\times5.5)=0.12$. As Y_{sp} is negligible for this cable, $Y_s=0.12$. From Table XIII, $Q=1.07$, and therefore, from equation 16, $Y_t=0.02\times6.10\times2\times1.07=0.26$.

Adding, $Y_c+Y_s+Y_t=0.64$. Thus, R_{ac}/R_{dc} at 30 degrees centigrade = 1.64. Consulting Table XIV, we see that R_{ac}/R_{dc} at 75 degrees centigrade = 1.53.

Discussion of Results

It is evident from the data that the construction of the protective covering, which for convenience we have called the "shield," may have a large effect on the losses. With a shield of very low resistance, the losses due to circulating currents and proximity effect in the shield may constitute 30 per cent of the total loss, or 50 per cent of the excess of a-c over d-c loss in the case of a 2,000,000-circular mil conductor. With smaller conductors this effect is much smaller, but is still of an important magnitude. Ordinarily, there is no justification in using a shield of resistance low enough to contribute to the losses to so large an extent. However, there are conditions, such as for example, to provide a path for carrier currents, which might make a continuous low resistance shield highly desirable and warrant acceptance of the resulting higher loss.

It is appropriate to develop the matter of shield resistance further. The "shields" on the cables here involved have generally consisted of two 3-mil copper tapes intercalated with non-metallic tapes or with each other, and two D-shaped copper wires, or skid wires, applied thereover, double start. The d-c resistance of the two 3-mil intercalated copper tapes is of the order of 300 microhms per foot of cable, which approximates closely the resistance of a copper tube with 6-mil wall, indicating that the contact resistance of copper to copper is extremely low. A method of correcting this condition is to intercalate the tapes with nonmetallic tapes, which results in producing a resistance in the two 3-mil copper tapes alone of about 5,000 microhms per foot of cable. However, the two skid wires (100 by 200 mils), which form a parallel path to the copper tapes, have a resistance of about 1,000 microhms per foot of cable, and the over-all resistance becomes about 250 microhms per foot of cable for the lower resistance shield and about 835 microhms per foot of cable for the higher resistance shield. In other words, in the case of the lower resistance shield the copper tapes are the main factor in determining the over-all resistance, whereas in the case of the higher resistance shield the skid wires are the main factor.

The matter of contact resistance between metal surfaces has not, in the opinion of the authors, received the attention that it merits. From limited experimental data not reported here, it appears that while two bright copper tapes intercalated with each other have very low contact resistance, two oxidized copper tapes have so high a contact resistance that the resistance of two such tapes intercalated with each other is no different than if they were separately intercalated with nonmetallic tapes. These data indicate further that there also is a satisfactorily high-contact resistance between bright copper and bright aluminum and between two bright aluminum tapes. Thus, if an entirely metallic shield is desired, any one of the last three mentioned alternatives is probably practical. Still another alternative would be to use tapes of higher resistivity, such as a high-resistance bronze or one of the nickel alloys, with attendant higher cost, however.

With any of the arrangements just mentioned, paralleled by two 100 by 200 mil copper skid wires, the resistance would be no higher than of the order of 850 microhms per foot of cable, because, as stated already, the skid wires are the chief determining factor of the resistance. In the case of the 2,000,000-circular-mil cable (number *3A*) the circulating current loss with a shield of this resistance is about 12 per cent of the d-c conductor loss. Suppose that with the same skid wire arrangement only one copper tape, with suitable intercalation, were used, the circulating loss would be reduced by only about 1 per cent in the case cited. Suppose that instead of using two skid wires, double start, only one skid wire were used, with one-half the lay (that is, the same separation between successive convolutions), the skid wire resistance would then be about 4,000 microhms per foot of cable and the parallel resistance with a tape structure having a resistance of 5,000 microhms per foot of cable would be about 2,200 microhms per foot of cable and the circulating current loss would be reduced from 12 per cent to about 4.5 per cent of the d-c conductor loss. One might go further and substitute skid wires of smaller cross-section or higher resistivity, but it should be noted that the largest gain possible is that represented by the loss due to the shield circulating current, which, with the higher resistance shields used in the measurements, is a relatively small portion of the total loss.

Mention has been made of the proximity effect loss in the shield. This is important only in the case of the low-resistance shields and is entirely negligible with those of higher resistance. It should be noted that there is no proximity loss in the skid wire portion of the shield because of the open spiral application.

The tests on segmental conductors reported here have been confined to treated segmental strand having three insulated segments and a bronze binder of about 40 per cent conductivity applied with a slight lap. A limited amount of experimental work also has been done on "treated" and "untreated" segmental strand, with various type binders and with both 2-segment and 3-segment insulation. The indications from these limited data are that with three insulated segments the conductor losses are affected very little by the foregoing variables, whereas when only two segments are insulated the effect of some of the variables on the conductor loss may be important. In this connection, it may be noted that the 2,500,000-circular mil segmental conductor reported by Wiseman,[1] which has two segments insulated and is untreated, has very much higher losses than would be obtained on treated strand with three insulated segments, based on data reported here. It is hoped that further study along the lines indicated in this paragraph can be pursued at an early date. However, segmental strand with three insulated segments is an effective means of keeping down conductor proximity losses.

It also may be stated that some measurements have been made on experimental segmental strand in which an insulating tape is inserted between the outer layer of wires in each segment and the inner layers. Preliminary measurements indicate that it may be possible by this means to reduce the conductor skin and proximity effect losses by a very material amount even from that obtainable with ordinary 3-segment insulation. Further work will have to be done before a definite report can be made. It is well to note, however, that in pipe-type cables the loss in the pipe itself is so large a part of the total loss that it is questionable whether there would be sufficient practical value in obtaining losses in the conductors much below what is obtainable with treated normal segmental strand having three insulated segments.

Consideration also might be given to the use of concentric conductors stranded with enamelled wires, which should have no proximity effect. With conductor proximity loss eliminated, the over-all loss in steel pipe may approach that with segmental conductors. The cost of such a conductor may be reduced by omitting the enamel on alternate wires of alternate layers, thereby still retaining at least one layer of enamel at every junction of adjacent wires.

At times the question has been raised as to the effect of short circuits occurring between segments of a segmental conductor. Theoretical considerations indicate that a single short circuit can have no effect on the losses, and multiple short circuits on the same segments, if spaced several lay lengths from each other, can have but inappreciable effect. The worst condition should theoretically occur if the short circuits are exactly one-half lay length apart, but even with such a condition the increased loss would occur only in the few feet between short circuits and would be insignificant with respect to the over-all loss. The matter was investigated with results shown in Appendix III. In these measurements, short circuits were deliberately inserted at each half-lay point of the entire 20-foot section of one of the conductors under test, and under this condition a maximum increase of 1.5 per cent of the d-c loss was noted with the cable in pipe. The short circuits were of a very low order of resistance. It may be concluded from these data that accidental short circuits between segments of segmental strand are of no practical consequence.

Data are given in Appendix IV of losses of pipe-type cable with 800,000-circular-mil Compack round conductors. Compack is a trade name describing a conductor in which all strands are applied with the same direction of lay and heavily rolled at each layer to produce a very compact assembly of wires. Analysis of the data indicates that the over-all losses are somewhat lower than would be indicated by Wiseman's[1] data. The measured ratio of a-c to d-c resistance in 6-inch pipe with closed triangular configuration is 1.23 at 30 degrees centigrade. Computation from Wiseman's formulas yields a value of 1.28 after addition of 0.033 for shield circulating current loss which Wiseman's cables did not have. Further analysis of the data shows that the indicated proximity loss in pipe is about the same as in air for this cable, instead of being nine times as great by Wiseman's formula. It will doubtless be desirable to investigate this matter further. Theoretical considerations indicate that proximity loss in a unidirectional strand should be much lower than in the usual construction of alternating direction of lay for successive layers of strand.

On the basis of the data and equations presented a tabulation has been prepared of losses in pipe of segmental conductor cables ranging from 1,000,000 to 2,000,000-circular mil in steps of 250,000 circular-mil, with insulation thicknesses of 315, 480 and 560 mils and the following construction details:

1. Number of insulated segments—3.
2. Binder—5-mil 40 per cent or lower conductivity bronze tape intercalated with a paper tape.
3. Shield—one or two copper tapes, each

intercalated with a nonmetallic tape.

4. Skid wires—D-shaped copper 200 by 100 mils, applied double start with spacing of 1 to $1^1/_4$ inches between successive convolutions.

The losses have been computed with $K=3.8$ for conductor proximity loss and $K_1=0.02$ for pipe loss and are shown for 75 degree centigrade copper temperature for 315-mil insulation and 70 degrees centigrade for 480- and 560-mil insulation. These values are given in Table XV for triangular configuration and Table XVI for cradle configuration.

Analysis of the losses as shown in Tables XV and XVI shows that the overall losses for a given conductor size and configuration are surprisingly alike for the different insulation thicknesses. However, there are small, but perhaps important differences in the distribution of the losses.

Appendix I. Measurements—Methods and Accuracy

Apparatus and Methods

D-C Measurements

A standard Kelvin Bridge was employed for making all d-c resistance measurements.

A-C Measurements

A null a-c potentiometer method was employed for measuring the a-c resistance of the cables. The circuit is shown in Figure 3. The conductors under test were connected in a wye for 3-phase measurements and in series for single-phase measurements. The power was received from a bank of three single-phase transformers with secondaries connected in delta. The primaries of these transformers were connected through Variacs to a 3-phase step-type voltage regulator, the regulator being used for relatively coarse adjustments of current and the Variacs for fine adjustments. Currents in the three phases were accurately balanced. However, even a relatively large unbalance has generally been found not to affect the average a-c to d-c resistance ratio to any significant extent.

For both single-phase and 3-phase measurements, the reactive components of the conductor voltage drops are balanced out by means of astatic mutual inductors with primaries carrying the full conductor current. The resistance component is balanced with a resistance potentiometer carrying current from the secondary of a 160-to-1 current transformer, the primary of which carries the conductor current. The detector employed is an a-c galvanometer. The galvanometer field is energized by a phase shifter which permits a balance to be obtained first with the field in quadrature to the main current (inductance balance) and then with a field in phase with the main current (resistance balance). The standard resistances used with the potentiometer are noninductive. In the measurements reported here, three different standard resistances, of approximately 0.035, 0.065 and 0.10 ohm were used. In making the resistance determinations, the apparent a-c resistance was measured for each conductor, the average of the two or three measurements being taken as the average a-c resistance of the conductors.

The a-c potentiometer reads in steps of 0.1 per cent, but there is ample sensitivity, especially at the higher currents, to interpolate to one-fifth of this value. As the potentiometer readings were generally in the middle third of the scale, the over-all sensitivity was of the order of 0.04 per cent.

At the balance of the potentiometer, the following expression holds for the a-c resistance of the conductor

$$R_{ac}=\frac{Mr}{v}\cos\delta$$

where

R_{ac} = apparent a-c resistance of conductor under test
M = potentiometer setting, expressed as a decimal of the standard resistance
r = resistance of potentiometer in ohms
v = current transformer ratio
δ = phase angle of current transformer. This is about one degree at 160 amperes and about 30 minutes at 800 amperes in the transformers used. Thus, $\cos\delta=1$ for all practical purposes

A simplified vector diagram for the balanced condition is shown in Figure 4.

Skin effect measurements were made single-phase with two conductors placed parallel to one another and spaced nine inches between opposing surfaces. For 3-phase measurements, three test conductors were employed, the operation of the circuit being substantially the same as in the single phase case. The three conductors were placed in triangular or cradle configuration as desired.

A typical set of 3-phase data is given in Table XVII.

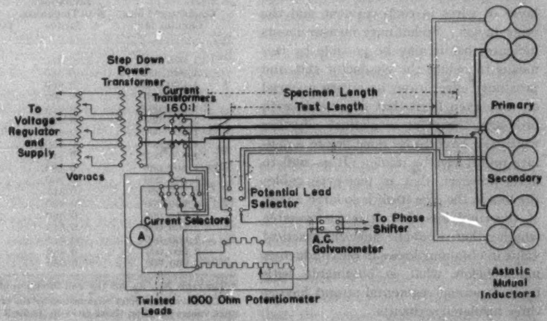

Figure 3. Schematic diagram of connections for a-c resistance measurements under 3-phase load

For single-phase measurements, one conductor and one mutual inductor are omitted

The wide variation in the apparent resistance of the three conductors has been observed whenever 3-phase measurements have been made. Indeed, with cradle configuration one of the readings is often negative. This has been observed by other investigators[3] and is due to dissymmetry of conductor and lead arrangement. However, while the individual readings do not truly reflect the division of losses in the individual conductors, the average value is the true average a-c resistance as in any other 3-wattmeter method of 3-phase measurement. Heat runs with triangular configuration have shown no significant differences in the temperature rise of the three conductors, indicating no large differences in loss actually generated in the individual conductors.

For single-phase measurements, potential leads from the east potential points were carried along the tops of the north and south conductors and contiguous thereto, to the west potential points, where they were twisted together and carried to the measuring circuit. This method of carrying the potential leads to the measuring circuit was found to give true skin effect indication in cases where these could be checked against accepted theoretical values.

Salter[2] in his recent paper discusses in detail the accuracy of various methods of disposing the potential leads. Our experience over a period of some 13 years has paralleled Salter's and we have arrived independently at the same solution.

For 3-phase measurements in air, the potential leads from the three potential points at the east end were twisted together, and carried perpendicularly to a point $1^1/_2$ feet above the cables. From there they were carried parallel to the cables to a point perpendicularly above the west end potential points where they were joined by the three twisted leads from the west end potential points. From this point, all six leads were twisted together and carried to the measuring circuit.

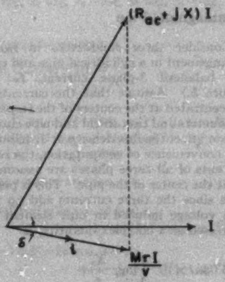

Figure 4. Vector diagram of a-c potentiometer circuit at balance

v = current transformer ratio I/i
δ = phase angle of current transformer
At Balance: $R_{ac}I = Mr\,i\cos\delta$. $\cos\delta \cong 1$

When the cables were placed in the pipe, the potential leads from the three potential points at each end were twisted together and carried away perpendicularly from the cables through holes in the pipe opposite the potential points. They were then carried to the measuring circuit in the manner described for 3-phase measurements in air.

Calorimetric Determination of Pipe Loss

The portion of increase in the a-c resistance due to the pipe loss was determined by a calorimetric method.

The three cables were placed in the pipe, which was in a closed area, free of air currents. With the desired configuration of conductors, and shields insulated from one another, 3-phase current was passed through the conductors for a period of 10 minutes. By means of the Kelvin Bridge, the pipe resistance was measured each minute for a period of 10 minutes before the current was turned on; and each minute for a period of 10 minutes after the current was turned off. From these readings, the rise in the pipe resistance during the 10-minute period that the current was on, was determined.

After a suitable rest period there was passed through the pipe for 10 minutes direct current of such magnitude as to produce substantially the same resistance increase as was produced during the a-c run. In order to predetermine the necessary magnitude of this current it was usually necessary to make one or more trial runs. As in the case of the a-c run, pipe resistance was measured by means of the Kelvin Bridge each minute during the 10-minute period immediately preceding and that immediately following the current run, and from these measurements the resistance increase determined.

During the a-c run, heat was being generated in the conductors as well as in the pipe and some of the heat from the conductors was being transferred to the pipe. Thus, the increase in pipe resistance was due to both the heat generated in the pipe and (to a small extent) that transferred to the pipe from the conductors. In order to reproduce this condition during the d-c run, while direct current was being passed through the pipe, a direct current of a different magnitude was simultaneously passed through the three conductors in series. The magnitude of the conductor current was such as to produce substantially the same heating effect in the conductors as did the alternating current. From previous a-c resistance measurements, an estimate of the skin-proximity loss of the conductors, sufficiently accurate for this purpose, can be made, and the necessary value of direct current to be passed through the conductors calculated. Thus, estimating 10 per cent skin-proximity effect in a given case, the direct current which must be passed through the conductors should be $\sqrt{1.10}$ times the current used during the a-c run.

The watts fed into the pipe during the d-c run being known, the watts generated in the pipe during the a-c run can be calculated readily by multiplying the d-c value by the ratio of the pipe resistance increase during the a-c run to that during the d-c run.

The probable accuracy of this calorimetic method is believed to be about 3 per cent of the pipe loss.

A set of data and a sample calculation for the determination of pipe loss are given in the example below.

Example

Given three 1,500,000-circular-mil segmental conductors in 6.10-inch inside diameter steel pipe; triangular configuration; 2.09 inch center-to-center spacing.

A-c Run. 783 amperes, 3-phase, through conductors for 10 minutes. Average d-c conductor resistance during run—106.9 microhms.

D-c conductor watts $=3\times783^2\times106.9\times10^{-6}=197$ watts. Increase in pipe resistance in 10 minutes—0.29 microhm.

D-c Run. 430 amperes, direct current, through pipe for ten minutes. (Simultaneously 840 amperes were passed through the three conductors in series on the basis of estimated 15 per cent skin-proximity loss, that is, $783\times\sqrt{1.15}=840$.)

Average pipe resistance during d-c run—183.2 microhms, and therefore watts fed into pipe during d-c run $=430^2\times183.2\times10^{-6}$, or 33.8 watts. The increase in pipe resistance in 10 minutes was 0.32 microhm. Calculating, the loss in pipe during a-c run $=33.8\times(0.29/0.32)$, or 30.6 watts. D-c conductor loss during a-c run equals 197 watts, and therefore pipe loss equals 30.6/197 or 0.16 in terms of d-c resistance of the conductor.

Accuracy of Resistance Measurements

D-C Measurements

A Leeds and Northrup standard Kelvin Bridge, with a suitable d-c galvanometer and scale, was employed for making the d-c resistance measurements. Numerous checks against known laboratory resistances established the accuracy of these measurements to be better than ±0.1 per cent.

A-C Measurements

Possible sources of error in the a-c measurements and how they are taken care of will be indicated.

1. The out-of-phase component of the conductor voltage drop is balanced out by voltage from the secondary of a mutual inductor, the primary of which carries the full conductor current. The primary lead and the primary coil are made of a cable employing a litz-wire construction. Thus, quadrature between the secondary voltage and conductor current is assured. Both the primary and secondary windings are astatic, thus assuring a minimum of interference from stray fields.

The use of a mutual inductor taking its primary current directly from the line is believed to be unique. Salter,[3] following common practice, takes the primary current for his mutual inductor from the secondary of a current transformer with primary carrying the full conductor current. With such an arrangement, correction must be made for the phase angle of the current transformer, and the phase angle must be known very accurately.

2. The in-phase component of the conductor voltage drop is balanced by a resistance potentiometer which takes its current from a current transformer, the primary of which is in series with the conductor. The cosine of the phase angle of this current transformer appears in the resistance balance formula as a multiplying factor. However, the phase angle of the current transformer used is no greater than one degree under the conditions of the test, and thus the cosine is 0.9998 or higher and may be regarded as unity for all practical purposes. The ratio of the current transformers, as calibrated recently, ranges from 160.0 to 160.2 over the range of currents used in the measurements and a ratio of 160.1 has been used for computing resistances at all currents, introducing a maximum error of ±0.06 per cent.

The standard resistances used with the potentiometer are essentially noninductive and are calibrated by means of the same Kelvin Bridge as was used for the d-c measurements. It should be noted that a small phase angle in the standard resistance is unimportant for the same reason as given for the phase angle of the current transformers.

3. A possible source of error is variation in the temperature of the conductors between the start and finish of a series of measurements. A technique was developed whereby the current was turned on only momentarily for each adjustment of the potentiometer or of the mutual inductor when balancing, thus heating up the conductor to an insignificant extent during a given series of measurements. D-c resistance measurements were made just before and just after each series of a-c measurements and, as illustrated in Table XVII, changed by only a small fraction of 1 per cent.

Several checks and comparative measurements with other laboratories were made for greater assurance of accuracy of the a-c resistance measurements, as detailed later.

When the equipment used in the present tests was first assembled, about ten years ago, a calibration measurement was made on copper tubes of 1.90 inch outside diameter and 1.49 inch inside diameter. A-c to d-c resistance ratio was measured with 30-inch separation at 20 degrees centigrade. The measured values were 1.005 and 1.006 for the two conductors, as compared with a theoretical skin effect value of 1.010.

The conductors were then brought together to a center-to-center separation of 2.26 inches. Two determinations of the ratio gave values of 1.307 and 1.310, respectively, at 400 amperes. The computed ratio from accepted theory[5] is 1.310.

In the foregoing measurements the distance between potential points was 18 feet.

During the course of the present series of measurements cable *3A* (2,000,000 circular mils) together with the 6-inch (nominal) inside diameter steel pipe were sent to the Electrical Testing Laboratories for comparative measurements with their equipment. Comparative values are given in Table XVIII.

Table XVIII. Comparative Tests with ETL 2,000,000-Circular-Mil Segmental Cable
Spacing 2.42 Inches, Center-to-Center, Shields Short Circuited

	A-c to D-c Resistance Ratio Authors	ETL
Triangular configuration, in air, 3-phase measurement	1.19	1.205
Triangular configuration, in 6-inch inside diameter steel pipe, 3-phase measurement	1.63	1.65

The ETL measurements in pipe were made with 15 feet between potential points, according to their standard method. Our measurements were made with 20 feet between potential points. The ETL measurements were at about 600 amperes, while ours were at 640 amperes. The agreement is satisfactory considering that the measurements were made with two separate setups.

Another check on our apparatus was obtained while making joint studies with Philadelphia Electric Company. An electrodynamometer-type wattmeter was supplied by Philadelphia Electric Company and connected into the circuit so as to measure the watts loss in each conductor simultaneous to measurement by the a-c potentiometer. The cable was installed in a 6-inch inside diameter steel pipe, in equilateral triangular formation. The shields, including skid wires, were touching throughout the test length. Comparative values between the wattmeter and the potentiometer method are shown in Table XIX. It is to be observed that the two methods checked each other extremely well. The watts loss listed under the a-c potentiometer column were calculated from the measured value of the a-c resistance, by using the measured value of conductor current.

Table XIX. Comparative Wattmeter and Potentiometer Readings

	Total Watts Loss Wattmeter	A-c Potentiometer
Room temperature (31 degrees centigrade)	713	714
At final conductor temperature (68.5 degrees centigrade)	732	736

Note also the measurement of skin effect of a round conductor reported in Appendix IV, on which the measured value was 1.056, as compared with a theoretical value of 1.057.

The check measurements given appear to give an excellent check on the a-c measurements. It is believed that the probable accuracy of these measurements is within ±0.5 per cent or better in all cases.

Appendix II. Pipe Loss in a Balanced 3-Phase Pipe-Type System

Nonmagnetic Pipe

Consider three conductors in random arrangement in a cylindrical pipe and carrying balanced 3-phase current, I. (See Figure 5.) Assume that the currents are concentrated at the centers of the respective conductors and that shield and pipe currents do not affect the flux density or distribution. For convenience of computation, the return currents of all three phases are assumed to be at the center of the pipe. This is permissible since the three currents add up to 0. The voltage induced in pipe element $r\,t\,d\theta$, expressed as a complex quantity, is

$$e=5.08\omega I\times10^{-9}\left(\log_e\frac{X_1}{r}+\frac{-1+j\sqrt{3}}{2}\log_e\frac{X_2}{r}+\frac{-1-j\sqrt{3}}{2}\log_e\frac{X_3}{r}\right)$$

$$=5.08\omega I\times10^{-9}\left(\log_e x_1+\frac{-1+j\sqrt{3}}{2}\log_e x_2+\frac{-1-j\sqrt{3}}{2}\log_e x_3\right) \quad (17)$$

or

$$e=5.08\omega I\times10^{-9}\times\sqrt{\begin{matrix}(\log_e x_1)^2+(\log_e x_2)^2+(\log_e x_3)^2-\\ \log_e x_1\log_e x_2-\log_e x_2\log_e x_3-\log_e x_3\log x_{1e}\end{matrix}} \quad (18)$$

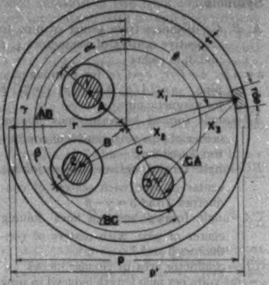

Figure 5. Graphic representation of notation in deriving pipe loss formula

$a=A/r_1$ $b=B/r_1$ $c=C/r_1$ $x_1=X_1/r_1$ $x_2=X_2/r_1$
$x_3=X_3/r$

The resistance of pipe element $rtd\theta$, in ohms per inch length, being $\rho\times10^{-6}/rtd\theta$, the watts loss per inch length in the element $rtd\theta$ is

$$dw=\frac{e^2rtd\theta}{\rho\times10^{-6}}=\frac{25.8\omega^2I^2rt\times10^{-12}}{\rho}\times\\ [(\log_e x_1)^2+(\log_e x_2)^2+(\log_e x_3)^2-\log_e x_1\\ \log_e x_2-\log_e x_2\log_e x_3-\log_e x_3\log_e x_1]d\theta \qquad (19)$$

and

$$w=\frac{25.8\omega^2I^2rt\times10^{-12}}{\rho}\times\\ \int_0^{2\pi}[(\log_e x_1)^2+(\log_e x_2)^2+(\log_e x_3)^2-\\ \log_e x_1\log_e x_2-\log_e x_2\log_e x_3-\log_e x_3\times\\ \log_e x_1]d\theta \qquad (20)$$

This may be written as

$$w=\frac{6.45\omega^2I^2rt\times10^{-12}}{\rho}\times\\ \int_0^{2\pi}[(\log_e x_1^2)^2+(\log_e x_2^2)^2+(\log_e x_3^2)^2-\\ \log_e x_1^2\log_e x_2^2-\log_e x_2^2\log_e x_3^2-\\ \log_e x_3^2\log_e x_1^2]d\theta \qquad (21)$$

By the law of cosines

$$x_1^2=1+a^2-2a\cos(\theta+\alpha)\\ =[1-a\epsilon^{j(\theta+\alpha)}][1-a\epsilon^{-j(\theta+\alpha)}]$$

$$x_2^2=1+b^2-2b\cos(\theta+\beta)\\ =[1-b\epsilon^{j(\theta+\beta)}][1-b\epsilon^{-j(\theta+\beta)}]$$

$$x_3^2=1+c^2-2c\cos(\theta+\gamma)\\ =[1-c\epsilon^{j(\theta+\gamma)}][1-c\epsilon^{-j(\theta+\gamma)}] \qquad (22)$$

Substituting these values of x_1^2, x_2^2 and x_3^2 in equation 21 we have

$$w=\frac{6.45\omega^2I^2rt\times10^{-12}}{\rho}\times\\ \int^{2\pi}[g_1^2+2g_1g_2+g_2^2+h_1^2+2h_1h_2+h_2^2+\\ m_1^2+2m_1m_2+m_2^2-g_1h_1-g_2h_2-\\ g_2h_1-g_1h_2-g_1m_1-g_1m_2-g_2m_1-\\ g_2m_2-h_1m_1-h_1m_2-h_2m_1-h_2m_2]d\theta \qquad (23)$$

The 21 terms of equation 23 may be integrated separately and will yield

$$w=\frac{25.8\pi\omega^2I^2rt\times10^{-12}}{\rho}\times\\ \sum_{n=1}^{\infty}\frac{a^{2n}+b^{2n}+c^{2n}-a^nb^n\cos n\underline{|AB}-b^nc^n\cos n\underline{|BC}-c^na^n\cos n\underline{|CA}}{n^2}$$

or

$$w=\frac{25.8\pi\omega^2I^2rt\times10^{-12}}{\rho}Q \qquad (24)$$

Now

$$Y_t=\frac{w}{w_c}$$

and

$$w_c=\frac{3I^2\rho_c\times10^{-6}}{0.25\pi(CI)}=\frac{3.82I^2\rho_c\times10^{-6}}{(CI)}$$

Therefore

$$Y_t=\frac{25.8\pi\omega^2rt(CI)Q\times10^{-6}}{3.82\rho\rho_c}$$

or

$$Y_t(\text{nonmagnetic})=\frac{1.51p't(CI)Q}{\rho\rho_c}\quad\text{at 60 cycles} \qquad (14)$$

Magnetic Pipe

If the pipe material is magnetic, only the inner portion of the wall thickness of the pipe will carry induced current. As a first approximation it may be assumed that the portion of wall thickness carrying the current is the same as the depth of penetration. From the data in Table II the depth of penetration at the current giving the highest a-c resistance is 12.2×0.28/159=0.0215 inch for the 6-inch pipe, and 7.65×0.32/152 =0.0161 inch for the 8-inch pipe. Substituting in equation 14 the above depths of penetration for t, the values given in Table II for ρ and 0.72 for ρ_c (resistivity of copper at 30 degrees centigrade, adding 2 per cent for stranding and cabling of segments), and replacing p' by p, the right-hand member of equation 14 becomes 0.0079 p (CI) Q for the 6-inch pipe and 0.0066 p (CI) Q for the 8-inch pipe, as first approximations.

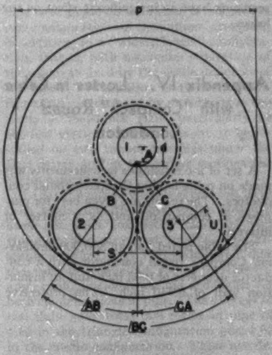

Figure 6. Cables in equilateral triangular configuration in magnetic pipe

$a=2A/p_1$ $b=2B/p_1$ $c=2C/p_1$ $s=2S/p_1$
$u=2U/p$
$b=c=1-u$

$$a=\sqrt{b^2-s^2/4}-\sqrt{\frac{3}{2}}s$$

$\underline{|AB}=\underline{|CA}=\sin^{-1}s/2b$
$\underline{|BC}=2\sin^{-1}s/2b$

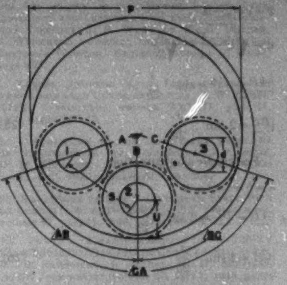

Figure 7. Cables in cradle configuration in magnetic pipe

$a=2A/p_1$ $b=2B/p_1$ $c=2C/p_1$ $s=2S/p_1$
$u=2U/p$
$a=b=c=1-u$
$\underline{|AB}=\underline{BC}=2\sin^{-1}s/2b$
$\underline{|CA}=4\sin^{-1}s/2b$

However, the presence of the magnetic material not only increases the flux but also tends to concentrate the flux in the material of the pipe, thus producing higher losses than calculated with the foregoing assumptions.

Calorimetric determinations of the loss in the two steel pipes used in the measurements reported in the paper (see Table VII) have indicated that the numerical factors in these expressions are about 2.6 times the values indicated, that is to say, 0.020 for the 6-inch pipe and 0.017 for the 8-inch pipe. For conservatism, and because the 6-inch pipe more nearly represents the type of pipe likely to be used in pipe installations, it is recommended that 0.020 be used. Thus,

$$Y_t\begin{pmatrix}\text{magnetic}\\\text{60 cycles}\end{pmatrix}=0.020p(CI)Q\text{ at 30 degrees centigrade} \qquad (16)$$

Evaluation of Q for Practical Cases

The evaluation of Q for random distribution of the cables in the pipe is a time-consuming process. Generally, however, cables are considered to be arranged either in equilateral triangular configuration or in cradle configuration, as shown graphically in Figures 6 and 7. For these cases the various distance ratios and angles involved are subject to considerable simplification.

Thus, for equilateral triangular configuration

$$b=c=1-u$$

$$a=\sqrt{b^2-\frac{s^2}{4}}-\sqrt{\frac{3}{2}}s$$

$$\underline{|AB}=\underline{|CA}=\sin^{-1}\frac{s}{2b}$$

$$\underline{|BC}=2\sin^{-1}\frac{s}{2b} \qquad (25)$$

For cradle configuration

$$a=b=c=1-u$$

$$\underline{|AB}=\underline{|BC}=2\sin^{-1}\frac{s}{2b}$$

$$\underline{|CA}=4\sin^{-1}\frac{s}{2b} \qquad (26)$$

Note that $\cos\phi=\cos(-\phi)$.

Thus, in evaluating say $\underline{|AB}$ for the purposes of the equation for Q it is immaterial whether α is subtracted from β or β is subtracted from α. It will be most convenient to subtract in a manner which will produce a positive angle.

It should be noted further that equations 25 apply to any equilateral triangular arrangement, regardless of whether or not the cables touch the inner pipe surface; also that equations 26 apply to any arrangement wherein all conductors are equally distant from the center of the pipe and the two outside cables are symmetrical with respect to the center cable.

Where adjacent cables are touching, as they are normally considered to be, u for both equilateral and cradle configurations will be equal to the over-all radius of the cables and very nearly equal to $s/2$. Table XIII gives the values of Q for this condition. The values of Q for both the equilateral triangular and cradle configurations in the broad sense explained before are given graphically in Figure 2.

Appendix III. Effect of Accidental Short Circuits Between Segments

A series of tests was performed to determine the effect of accidental short circuits between segments. In order to accentuate the effect, the measurements were made with short circuits deliberately imposed at frequent intervals. The results of these tests are given in Table XX.

The short circuits were placed in the top conductor only. Copper wedges, driven between adjacent segments, served as the short circuits for these determinations. The effective resistance of these short circuits was 65±20 microhms. Short circuits between bare and opposite segments were obtained by removing the segment insulation from the segment opposite the bare segment. Copper wedges were driven between the bronze binder tape and the insulated opposite segment at the place where the insulation was removed. The effective resistance of these short circuits was 345±50 microhms.

From the results, it is evident that the short circuiting of the bare segment with either an adjacent or the opposite insulated segment by means of several low-resistance short circuits spaced one-half lay length apart has no measurable effect on the a-c resistance of a segmental cable system in air. Similar short circuits have measurable but slight effect on the a-c resistance of cables in steel pipe. It may be concluded that occasional accidental short circuits between segments have an insignificant effect on the losses.

Table XX. Effect of Short Circuits

Cable 1B with Shield Removed—Triangular Configuration (S=2.35 Inches)

	Three-Phase A-c to D-c Resistance Ratio
Short Circuits Between Bare and Adjacent Segments	
Cable in Air	
No short circuits	1.022*
Short circuits at each lay length	1.023
Short circuits at each one-half lay length	1.023
Short circuits at each one-half lay length, but top conductor rotated 90 degrees	1.023
Cable in 6.10-Inch Inside diameter Steel Pipe	
No short circuits	1.178
Short circuits at each one-half lay length	1.188
Short circuits at each one-half lay length, but top conductor rotated 90 degrees	1.194
Short Circuits Between Bare and Opposite Segments	
Cable in Air	
No short circuits	1.027*
Short circuits at each lay length	1.027
Short circuits at each one-half lay length	1.027
Cable in 6.10-Inch Inside Diameter Steel Pipe	
No short circuits	1.180
Short circuits at each one-half lay length	1.186

* Difference between these two values probably due to some difference in separation.

Appendix IV. Losses in Cable with "Compack" Round Conductors

A set of a-c resistance measurements was made on cable having Compack round conductors. The results are given here for purposes of comparison and as a matter of interest.

The cable tested had an 800,000-circular-mil Compack round conductor with a conductor diameter of 0.95 inch and an insulation wall of 0.540 inch. The protective

shield consisted of two 3-mil copper tapes, each intercalated with a 7-mil polyethylene tape, with two 0.100- by 0.200-inch skid wires, applied double start, with a spacing of $1^1/_4$ inches between successive convolutions.

Measurement of skin effect produced a value of 1.056. This compared with a value of 1.057 as calculated from accepted formulas for round homogeneous conductors.

Results of 3-phase measurements in air and in steel pipe are given in Table XXI.

Discussion

C. T. Hatcher (Consolidated Edison Company of New York, Inc., New York, N. Y.): Proper selection of cable size to meet carrying capacity requirements has been a troublesome phase in the engineering of pipe cable lines, especially in the case of the heavier circuits installed during the past few years. Basic technical data were limited with respect to vital factors involved in the rating of these systems—namely, component a-c losses and thermal resistance of the soil.

Considerable research has been carried on during that time on both of these subjects and the situation today is considerably improved. Basic data are being obtained, and the underlying theory governing effect is being developed.

This paper is a major contribution to our knowledge of the behavior of a-c losses in pipe cable systems and a very necessary supplement to Mr. Wiseman's Insulated Power Cable Engineers Association[1] report. As a result of these two studies, the general theory has been more adequately developed and, with the more complete understanding now furnished of the component sources of a-c losses in pipe, the direction of attack towards reduction of these losses becomes apparent.

The authors have not claimed to offer a complete answer to the problem and, because of the number of variables involved, further tests are deemed desirable. The need for additional test data has been recognized generally by the industry. Some months ago the Consolidated Edison Company was confronted with the need for specific data in order to evaluate properly design features proposed by cable manufacturers for several projected 138-kv pipe cable lines. A research program, to be conducted by Electrical Testing Laboratories, was authorized for study of the component losses in cables of 1,500,000-circular-mil size. Because of the concurrent interest of other utilities, an Association of Edison Illuminating Companies—Edison Electric Institute Working Group was appointed to sponsor further research on this subject. In setting up the Consolidated Edison Company research program, the cable manufacturers and members of the AEIC—EEI Working Group were invited to participate in a series of discussions with a view to formulating a comprehensive program of research which might be correlated with possible further research under AEIC—EEI sponsorship.

The test program as set up at joint conferences was patterned very much after the lines pursued by Mr. Meyerhoff and Mr. Eager. Basic tests were to be made to determine: conductor loss; loss in shield and skid wires; and loss in pipe. Tests have been in progress for some months and a number of measurements of a-c/d-c resistance ratio have been made in air and in pipe on various samples of 1,500,000-circular-mil 138-kv cable from different manufacturers. All of these samples are of the "high resistance shield" type, corresponding approximately to sample 2*A* of the authors' tests. Three-phase measurements in air and in pipe were made on a number of samples in two configurations of the authors' tests and, in addition, in a "wide triangle" configuration, that is, with maximum separation of the cables as fixed by the inside diameter of the pipe. The addition of the latter configuration was dictated by an interest in the limits of resistance ratio, particularly as 300 feet vertical riser sections are to be installed on two tunnel crossings under the East River and in these riser sections the cables hang free.

To date no measurements of pipe loss have been made, and the data so far obtained have not been completely analyzed yet. However, the measured total a-c/d-c resistance ratios check reasonably well with the authors' computed values for the triangle configuration in air, but are higher for both configurations in pipe. The average of test data gave total loss ratios in pipe of 1.40 in the triangle configuration and 1.62 in the cradle configuration. These are dependent somewhat on details of construction.

The test results obtained in the "wide triangle" configuration indicate that values greater than those of the cradle formation may result with random lay in the field and this has been borne out by field test measurements made on two existing lines.

In their discussion of results, the authors have pointed out the line of attack in reducing the "shield" circulating current loss by increasing skid wire circuit resistance. Some tests have been made on samples with modified skid wire design which bear out this point, reductions of two-thirds or more in the "shield" circulating current loss having been obtained.

In the majority of tests made, measurements were obtained of the induced voltages in the "shield" circuits in air and in pipe. Measurements also were made, with tong ammeter, of the currents flowing under short circuit conditions in component parts of the "shield" assembly, insofar as these were separable. The indicated ratios varied considerably but on the average an increased loss in pipe over values in air of the order of 2.1 times for the close triangle configuration and 2.5 times for the cradle configuration was indicated. The over-all average ratio for all three configurations measured is 2.3.

Extra a-c losses are inherent in pipe-type construction. It is obvious however, that these losses can be reduced, some of them considerably so, by the use of proper techniques or choice of material. A number of steps in this direction are already underway and further improvement can be expected. The authors' paper illuminates the field for further research.

Losses in the conductors are considerably improved by the use of segmental construction in the larger sizes and it is possible that conductor loss can be still further reduced by insulating individual strands with some type of high resistance film which will suppress proximity effect.

Reductions of losses in shields and skid wire circuits were effected by the use of high resistance materials. As indicated by test data, increasing the circuit resistance by the use of low conductivity alloys and/or reducing the number and pitch of skid wires, can, for all practical purposes, eliminate the greater part of this seat of loss.

The authors and the General Cable Corporation are to be commended for carrying on this extremely valuable research which, when correlated with data now being obtained or planned by other manufacturers and utilities, will establish the necessary understanding for most economical design of the complete pipe cable system.

F. H. Buller (General Electric Company, Schenectady, N. Y.): For several years there has been a real need of data on the a-c/d-c ratio of cables in steel pipe and conduit. A good start was made on this problem in the paper on the Electrical Testing Laboratories tests on cables in steel pipe, presented by R. J. Wiseman before the AIEE in 1948. It was recognized at the time that additional information was badly needed especially on segmental conductors, and on the effect of losses in the shield and skid wire.

Mr. Meyerhoff and Mr. Eager appear to have made a substantial contribution along these lines. While the data they have presented are valuable and are badly needed, a few comments are in order.

Referring to Table III* and Table XI of the paper covering skin effect (Y_0), we have summarized the results given in those tables, in Table I of the discussion together with the calculated skin effect using multipliers of 2.0 and 2.3. It is evident from this table that the results given by the authors in their Table III and Table XI do not agree, and that on the 1,000,000- and 2,000,000-circular-mil sizes these results are appreciably lower than the test results, whereas on the 1,500,000-circular-mil size they are considerably higher than the tests. We are inclined to wonder if the test result on this size is not somewhat low. Furthermore, it is quite evident that the 2.3 multiplier is too high; the true multiplier should be around 2.1. This agrees with Mr. Wiseman's results presented in his paper.

Next with regard to Table IV of the paper, the computed results appear to agree with the test results within about 20 per cent (that is 20 per cent of the extra a-c loss, not 20 per cent of the a-c/d-c ratio) except in two cases. The two cases in question are designation *1A* short-circuited shield where the computed result is 50 per cent high and designation *2A* where the computed results are 50 per cent high on the insulated shield and 57 per cent high on the short-circuited shield.

It seems likely that the discrepancy in designation *1A* and designation *2A*, insulated shield, may be due largely to the difficulty in measuring small increments of loss, and possibly to the rounding off of the various figures involved. This is not true of designation *2A* short-circuited shield where the extra a-c loss is 7 per cent measured and 11 per cent computed. A series of tests now in progress on a conductor of this size appears to give 11 per cent for the extra a-c loss which agrees well with the calculation given in the paper. It would seem likely therefore that the test result of 7 per cent is low in this instance.

Table II. Values of Y_{sp} and Y_{sp} from Equations 12, 13, and Test

Conductor Size, Circular Mils	R_{cm}	R_s'	Cable in Air—Y_{sp}' Calc.	Cable in Air—Y_{sp}' Test	Cable in Pipe—Y_{sp} Calc.	Cable in Pipe—Y_{sp} Test
1,000,000	10.75	240	0.033	0.020	0.081	0.030
1,500,000	7.31	242	0.047	0.080	0.118	0.080
2,000,000	5.32	217	0.073	0.030	0.182	0.150

Incidentally, while 20 per cent is reasonably good agreement for cables in magnetic pipe between calculation and test, it does seem like a rather large discrepancy for cables in air. Possibly it might be well to refine the method of calculation to bring this discrepancy down, if this can be done.

An estimate of proximity loss in the shield Y_{sp} and Y_{sp}' in pipes and in air can be obtained from Table IV and Table V of the paper by comparing a-c/d-c ratio as measured on high-resistance shields where it is negligible and low-resistance shield where it is appreciable. Table II of the discussion compares the results obtained in this way with the calculations and equations 12 and 13 of the paper. It is evident from this table not only that the test results are somewhat erratic (probably a matter of taking the difference between small quantities), but that the equations do not agree with the test results at all. In our opinion much better agreement is needed before equations 12 and 13 can be used with any confidence.

The over-all discrepancy in a-c/d-c ratio in Table V of the paper ranges from −4 per cent to +18 per cent. This is probably about as good as could be expected in a magnetic pipe. The agreement in Table VI is even better, from −9 per cent to +9 per cent. This indicates that an empirical correction factor of from 10 to 20 per cent should be added to the losses calculated by the authors' equations if they are to be applied for practical use with a reasonable factor of safety. Incidentally, tests now in progress give a figure of 1.39 rather than 1.33, as in Table V of the paper, designation *2A*, shield short-circuited. It would seem therefore that Mr. Meyerhoff and Mr. Eager are running somewhat lower on their test results both in pipe and in air than other investigators. This is another reason which would justify the empirical correction factor just suggested.

In the paper there appears equation 6 for the quantity Y_{cp}' (conductor proximity effect) with segmental conductors. This equation and the subsidiary equation for X_1 with its coefficient $K=3.8$ for three insulated segments and 6.0 for two insulated segments, make it appear that proximity effect is very much less with three insulated segments than with two. The only possible cause of this difference is the short circuiting effect of the binder tape on the two uninsulated segments, and since this short circuiting effect is necessarily not very large it is very surprising that there should be such a difference in proximity effect between the two cases. We believe that the authors should support these *K* constants with extensive test data before they may be safely considered authoritative.

Appendix II involves a nice piece of mathematical work resulting in formulas for pipe loss in nonmagnetic pipes. As might be expected when it is attempted to apply these formulas to magnetic pipe, certain approximations as to depth of penetration are necessary, and rather large empirical multipliers are involved. Here again extensive test data are desirable to support these multipliers and this approximation before the results can be considered authoritative. We believe it would be of value to the industry if the authors saw fit to present these test data, and also the test data on which the *K* factor is based either before the AIEE or somewhere else in the technical press.

Finally, it is clear from the data presented in this paper that a nonintercalated shield is a bad business, and that much lower losses are obtained by intercalating the shielding tape.

J. H. Neher (Philadelphia Electric Company, Philadelphia, Pa.): It is in large measure due to the efforts of Mr. Meyerhoff and Mr. Eager as embodied in their excellent paper, that we are rapidly approaching the point where we can stop guessing and commence to calculate the loss components in a pipe-type cable system with reasonable assurance of coming somewhere near the right answers. And this process will be materially simplified if we look carefully at the fundamentals involved and in so doing discard a few cumbersome practices which have been dragged along from the past.

I refer specifically to the continued use of the a-c/d-c ratio concept. Fundamentally the losses consist of d-c losses and extra a-c losses. The former depend upon the temperature of the conductor, but the extra a-c losses originating outside of the conductor in the shielding tapes and pipe depend upon their respective temperatures which are only indirectly related to the conductor temperature. Furthermore the extra a-c losses originating in the conductors have such a slight dependence on conductor temperature that they may be considered as being independent of this temperature. This was noted by E. H. Salter in the Electrical Testing Laboratories tests[1] and is confirmed by the Arnold Theory of Skin and Proximity Effects.[2]

From a practical standpoint, therefore, a given problem is more conveniently solved by calculating the extra a-c losses at representative temperatures and expressing them in terms of an equivalent extra conductor resistance, since it is a value of resistance which we ultimately use, and then adding this resistance to the d-c resistance of the conductor at its operating temperature. The a-c/d-c ratio which changes with conductor temperature need not enter the calculation, but the net result is the same as that obtained by use of the formulas given in the paper.

---

* Editor's Note: The figures in Table III referred to by Mr. Buller appeared in the preprint of the author's paper, but were revised as noted in the author's closure before publication.

The authors choose to calculate the skin and proximity effects in air separately, although they are combined when calculating the net effect within the pipe. Actually they may be calculated together just as simply by using the particular version of the Arnold Theory cited in Mr. Wiseman's paper.[2] The relationship between the additional conductor loss in pipe and the loss in triangular configuration in air is given as an empirical equation, 7, in the paper but its development is not indicated. I have examined this relationship for all of the tests given in the paper and also the tests of the Electrical Testing Laboratories[1,2] and find that within the limits of expected accuracy this ratio is 1.5 for triangular configuration in conduit, 2.0 for triangular configuration in steel pipe, 1.7 for cradled configuration in conduit, and 2.3 for cradled configuration in steel pipe. In all cases these ratios are based on a triangular configuration in air of the given adjacent conductor separation.

In the case of segmental conductors, and also theoretically in the case of stranded conductors, the Arnold Theory employs a modification factor in formulating the argument used in the Bessel Functions (equation 6 of the paper) to determine the skin and proximity effects. This factor may be introduced in several different ways, and the authors' K is not the same as Arnold's K. It seems more desirable to effect this modification by introducing a factor F as a multiplier of the d-c resistance. Thus

$$x_1 = \frac{6.80}{\sqrt{FR_{dc}}} \tag{1}$$

For a solid conductor $F=1$ and this also applies for the concentric stranded conductor in the Electrical Testing Laboratories' tests. For the conductors covered in the paper, F is equal to 3.2, which is in effect the factor of merit of the conductor construction, since the higher the value of F, the lower the additional conductor losses for a given size of conductor.

The authors are to be commended on their mathematical persistence in solving for Q in equation 16 which represents the pipe loss component, but Q also can be obtained somewhat more simply by graphical integration. It would seem, however, that equation 16 may be improved by using R_e in preference to (CI). Thus

$$Y_t\left(\begin{matrix}\text{magnetic at}\\ \text{60 cycles}\end{matrix}\right) = 0.21\frac{pQ}{R_e} \tag{2}$$

The numerical constant in this equation applies to steel pipe. Based on the Electrical Testing Laboratories' tests,[1] the corresponding constant is 0.18 for conduit.

A. H. Kidder (Philadelphia Electric Company, Philadelphia, Pa.): The authors are to be commended for presenting so thorough a description of their recent tests on certain segmental cable constructions, together with approximate quantitative illustrations of relationships which become increasingly important in the design of heavy-duty pipe-type cable circuits. Their observations of total losses are thought to have sufficient accuracy to permit an approximate appraisal of the basic problem, which is to identify and control the factors which determine the efficiency of heavy-duty pipe-type cable designs.

The authors present over-all ac-dc ratios which bring us near but not quite to a complete qualitative understanding of the problem.

Designers of pipe-type circuits are confronted with the need to provide paths for transmitting loads of 1,000 amperes or more, through environments having heat dissipating characteristics which determine the maximum permissible watts losses, and in turn the maximum permissible resistance, or required conductance, of each such path. The cable designer then must select the particular cable construction and the conductor size which will provide the required conductance. The ratios which the authors have presented permit ready analysis from which it will become apparent that the conductance of a pipe-type circuit, however, may have little or no relation to the conductor size.

For example, consider Figure 1 of the discussion which has been constructed to illustrate the effects of steel pipe and cable configuration on 69-kv conductor size, using the information given in Tables X, XV, and XVI of the paper. If a resistance of 0.0125 ohm per 1,000 conductor feet will satisfy the given conditions, the corresponding conductance would be 80 mhos per 1,000 conductor feet. From the illustration it will be seen that the minimum conductor size would be 1,060,000 circular mils for use in nonmetallic pipe. For installations in steel pipe, the conductor size would be 1,300,000 circular mils if the three cables were to be triplexed, or 1,560,000 circular mils if the cables were to be cradled as in present conventional practice. Conversely, it is apparent that adoption of a triplexed construction would save 260,000 circular mils of copper cross-section in this particular case and that the use of a nonmetallic pipe would save an additional 240,000 circular mils. The cost of cables is very sensitive to conductor size. The opportunities for copper economy are substantially greater under conditions which require conductances in the order of 90 to 100 mhos, and could be converted into substantial cash savings by proper design, if there were some degree of consistency between identical tests on cables of apparently identical construction. A practical substitute for magnetic steel pipe apparently would solve the whole problem, or at least reduce considerably the need for improved cable designs. For the present, however, steel pipe must be included in the analysis.

The large uncertain effects of apparently trivial variations in cable design and inconsistencies between successive tests on cables of identical manufacture, suggest that a good bit of thought can be given profitably to consideration of methods for increasing the conductor efficiency in steel pipe installations. In Figure 2 of the discussion, for instance, I have plotted conductor size against 75-degree-centigrade conductance in triangular formation for several 69-kv pipe-type cable sizes. The heavy curve represents the construction for which the authors have estimated R_{ac}/R_{dc} in Table XV. Also shown and identified for

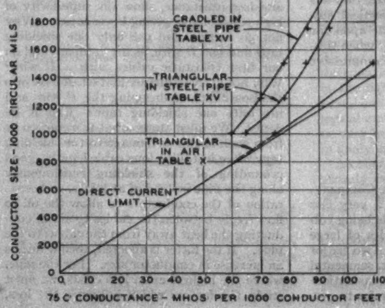

Figure 1. (left) Effects of steel pipe and cable configuration on 69-kv conductor size

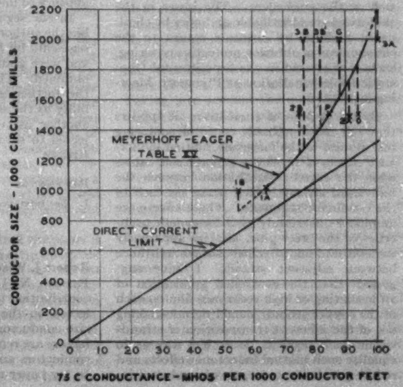
Figure 2. (right) Relation between 75 degree centigrade conductance and 69-kv pipe-type cable size for triangular configuration in steel pipe



comparison are tests reported by the authors in Table X for samples 1*A*, 2*A*, 3*A*, 1*B*, 2*B*, and 3*B*, together with corresponding data from four manufacturers' tests, 3*B'*, *G*, *O*, and *P*, made in conformity with certain purchase specifications with which I am familiar. Several significant observations become apparent from a study of these data:

1. The four, 2,000,000-circular-mil constructions have conductances the same as analysis of Table XV would indicate to be expected of conductors whose sizes range from 1,250,000 to 2,200,000 circular mils.

2. Similarly, the four 1,500,000-circular-mil constructions have conductances respectively the same as would be expected from Table XV for conductors whose sizes range from 1,200,000 to 1,850,000 circular mils.

3. The extra copper required to offset the higher losses in the authors' "low resistance shield" type of construction appears far out of proportion to any possible advantages that might be gained by its possible use as a path for carrying currents.

4. The fact that constructions 3*B* and 3*B'* may be considered to be identical and were tested in the same laboratory, suggests that slight variations in manufacture and perhaps even in handling the cables may have substantial effect upon their efficiency as conductors. The extra polyethylene-intercalated 3-mil copper tape of sample 3*B* hardly would account for its 5 per cent lower conductance.

The 1,500,000 circular mil sample *O* was probably the first on which a full-scale a-c loss test was made. The results were far better than had been expected, giving a conductance in the order of 94 mhos per 1,000 conductor feet. Test accuracy may have been less dependable than in later tests. It is therefore possible that this considerably older cable design had no higher conductance than the authors' sample 2*A* at 91 mhos.

The wide dispersion of test results suggests, however, that the respective constructions probably include some important indeterminate which should be brought under control before additional tests or increased test accuracy can have much value.

The inefficiency of the authors' novel "low resistance shield" construction can be avoided very conveniently by returning to the conventional use of intercalated insulation or the equivalent. The losses in the skid wires are identifiable and may be eliminated perhaps by eventual return to the canvas-type of abrasion protective covering, such as was used in the experimental Oilostatic cable installation at Plymouth Meeting in 1933.

By the process of elimination, it appears that the most probable cause of confusing test results is the uncertain mutual inductance effects of nearby segments and cables upon the current distribution between the individual strands which make up each of the conductor segments. These effects are amplified uncertainly by the magnetic properties of the steel pipe, also by apparently variable and uncontrolled contact resistance between adjacent strands. I have suggested[1] that the controlled application of an insulating or high-resistance film on each of the copper strands should permit making use of the inherent transposition of strands within each segment, in such a way as to equalize such mutual inductance effects and reduce proximity as a cause of conductor inefficiency. The authors' suggested possible use of enameled wires should not be nearly so effective with untransposed strands in concentric conductors, as with the transposition inherent in segmental construction, and I am not convinced that enamel is the answer. The authors' reference to the high contact resistance for aluminum suggests that aluminum strands might be more efficient than copper for large cables, despite the lower specific conductivity. A practical alternative may be the application of a very thin (possibly oxidized) aluminum film on the copper strands before the segments are stranded and compacted. Still another possibility is use of the conventional oxidized lead-coated copper strand, although it appears likely that the compacting pressures might make it less effective than aluminum. The use of a copper oxide or copper sulphide film might have similar advantages, but such films are thought to be more active catalysts than lead, aluminum, or their oxides. The method of joining conductors would, of course, have to be correlated with such a modification of the conductor strand.

1. 69-Kv Pipe-Type Cable Circuits in Philadelphia, A. H. Kidder, G. S. Van Antwerp. *AIEE Transactions*, volume 68, part I, 1949, pages 550–59.

W. A. Del Mar (Phelps Dodge Copper Products Corporation, Yonkers, N. Y.): This paper is of great value to the industry both for the wealth of experimental data and for the mathematical analysis which has required not only a knowledge of the physics involved, but even more, a well-balanced judgment in evaluating the many necessary assumptions and approximations.

That the authors have used these qualifications and have made the best use of Arnold's work is clear to me because I have been able to check values of a-c/d-c resistance ratio calculated by their method against laboratory test data and, using reasonable assumptions, find a very close agreement.

The practical use of the method would be helped if Figure 5 of the paper were supplemented either by a table from which large scale curves could be made, or by reference to Arnold's Table I[1] from which Figure 5 appears to have been plotted.

In our segmental compression cables we, like the authors, have avoided short circuiting segments by having only one bare segment and were gratified to find the low resistance obtained. The 3-segment construction has the further advantage of mechanical stability as the segments cannot slide upon one another as in a 4-segment cable, when subjected to severe longitudinally compressive stresses.

Robert J. Wiseman (The Okonite Company, Passaic, N. J.): This paper is a very fine contribution to the data which is being collected on the electrical properties of large size conductors in steel pipes. Two major factors are reported in this paper, segmental conductors and shielding of the insulation. In my paper which the authors refer to we, that is, the Insulated Power Cable Engineer's Association reported on concentric conductors and only one segmental conductor and also on nonshielded cables. As the authors state our results are more applicable to low-voltage rubber or varnished cambric cables and not high-voltage cables, yet they can be used for heavy-wall nonshielded cables in pipes.

I like very much the detailed information which the authors report and the development of the theoretical aspects of the various factors. It is good that they have given curves and tables for some of the terms used in the formulas. Otherwise some of us would not want to go through the calculations each time we had to determine a conductor size to carry a given current. It is desirable, if possible, to use as simple formulas as possible. Therefore, as a matter of interest I took the pipe loss as given in Table XV of the paper and computed it by the formula given in my paper, namely, $PL = 0.00150\ S^2/p$ ohm per 1,000 feet, where S is the spacing, center to center, for triangular spacing and p is inside diameter of pipe. Table III of the discussion compares the values given by the authors, column 3, with the above calculations, column 4. Likewise for the cradle configuration, I took the geometric mean spacing, that is $S' = \sqrt{S_1S_2S_3}$ and $PL = 0.00180\ S'^2/p$ ohm per 1,000 feet obtained the values shown in column 6 as compared to column 5 for the authors. The agreement is good considering that we are making assumptions which involve approximation.

I hope that time will be available later to see what can be done with proximity effect.

There is considerable information given in the paper which affords us a means for studying what is the order of magnitude of each of the factors which contribute to the extra a-c losses and how can they be reduced. For example, the authors use a 4-segment conductor and insulate three of the four segments. It is customary to insulate the two opposite segments. If we assume, as the authors do, that the skin effect of a 4-segment conductor is the same as that for a round conductor having 44 per cent of the area of the segmental conductor, then nothing appears to be gained by insulating three segments over two segments, as the Insulated Power Cable Engineer's Association tests made on a 2,500,000-circular-mil conductor gave the same result and two of these segments were insulated. Perhaps this could be investigated further.

The results on shielding losses, both high and low resistance, show the superiority of high resistance in giving lower losses. Why not go further and use only one shielding tape and one *D* wire, as my company did on our first Oilostatic cables with a *D* wire? Why not go even further and let us look into the possibility of dropping the *D* wire and use only one shielding tape? Can it be done? We must study what it means to us from such angles as damage to the shielding tape when installing long cable lengths, good grounding of the shielding continuously along the pipe instead of at joints, and separation of the conductors to allow the oil to flow freely between the cables to aid in conducting the heat away from the cables to the pipe. If the latter is affected, then it means an increase in conductor size. For the pipe, where the highest extra loss exists, we must study the factors which influence the loss,

* $PL = 0.00150\, S^2/\rho$ $\quad A = 1 - PL/R_{dc}$
** $PL' = 0.00180\, S'^2/\rho$ $\quad B = 1 - PL'/R_{dc}$

namely, spacing of the conductors, pipe diameter, and pipe material. Increase in the spacing between the conductors increases the loss for a given pipe size. Increasing the pipe size decreases the loss for both triangular and cradle configuration. As cradle configuration gives a higher loss than triangular formation, we should endeavor to keep the cables in triangular configuration. The nature of the pipe material is the major factor. Perhaps a nonmagnetic pipe of high resistance would be best, but its cost may be prohibitive. A magnetic pipe of low permeability may be helpful, but Dr. Hutchings of the British Electrical and Allied Industries Research Association has made calculations to show that using a steel of permeability of $\mu = 300$ and $\mu = 1{,}700$ gives about the same loss. Therefore, we would have to go under $\mu = 300$.

Table IV of the discussion gives total a-c/d-c ratios for some cables that we have tested.

Table IV

Cable	Ratio R_{ac}/R_{dc}	Temperature, Degrees Centigrade
3 single conductor, 1,500,000 circular mil, segmental $t = 0.315$ inch; $6^5/_8$ inch OD pipe	1.38	27.4
	1.27	65.8
3 single conductor, 500,000 circular mil, compact $t = 0.500$ inch, 6 inch OD pipe	1.19	32.3
3 single conductor, 350,000 circular mil compact	1.13	78.0
$t = 0.465$ inch; $5^9/_{16}$ inch OD pipe	1.08	68.2
3 single conductor, 500,000 circular mil $t = 0.560$ inch; number 10 American wire gauge	1.47	38.2
copper armor over insulation;	1.41	107.0
$6^5/_8$ inch OD pipe	1.45	46.0

The values for the 350,000-circular-mil circuit and the 500,000-circular-mil circuit (nonarmor) are the same as the Insulated Power Cable Engineer's Association[1] have set up for 3-conductor cables.

The results reported in this paper and the investigation now being made by the Electrical Testing Laboratories for the Association of Edison Illuminating Companies will supply us with plenty of data to analyze carefully and draw conclusions from, with the hope that we will arrive eventually at a construction that will give us an optimum value of extra a-c losses at a reasonable cost.

L. Meyerhoff and G. S. Eager, Jr.: The reception of the paper, as evidenced by the various discussions submitted, is highly gratifying. In general, there is agreement that the methods of computation given in the paper give a reasonably close approximation to losses measured by other observers. One of the discussors points out discrepancies between observed and calculated values and suggests that modifications of certain equations are in order for greater reliability. Another intimates that since there is so wide a range of losses with apparently identical constructions, too close correlation should not be expected.

All of the foregoing is in line with the statement in the early part of the paper that the data presented are not claimed or believed by us to constitute a complete answer to the problem. We concede that there are discrepancies among the data and between the data and calculations and that some of the equations may be subject to modification in the light of later information. We believe, however, that we have presented a logical mathematical approach which should be very helpful in planning future work and in analyzing other data.

A concrete accomplishment of the paper is already evident in the apparently complete acceptance that shield circulating current losses vary substantially according to equations 9 and 10 of the paper. Various lines of approach which were mentioned and analyzed in the paper have received attention, such as using shielding materials of higher resistance and using one *D*-wire instead of two, and the shield losses, within experimental error, have been found to vary inversely as the shield resistance, as the equations indicate. Mr. Hatcher's data indicate, however, that the ratio between shield loss in pipe and that in air may be greater than indicated by the paper.

Mr. Hatcher, Mr. Kidder, and Mr. Wiseman discuss further the matter of reduction of conductor losses by use of various devices which would increase contact resistance between the individual wires making up the strand. Enamel, copper oxide, copper sulphide, or aluminum coatings on the wires, if the coatings are not broken up too much in compacting, may all be very effective in reducing the proximity effect and probably also, to a lesser extent, the skin effect of segmental conductors. The scheme mentioned in the paper, where the outer layer of wires in each segment is separated from the other layers by an insulating tape, also might be effective to a somewhat smaller extent but would probably be less expensive and easier to splice. The use of enamelled concentric strand was suggested in the paper as a possible way of obtaining the same conductor losses as with ordinary segmental conductors, but with a possible cost saving. We agree with Mr. Kidder that concentric strand made with enamelled wires would have higher losses than segmental strand made with enamelled wires, provided, of course, that in the latter the integrity of the enamel coating is not seriously impaired by compacting.

Mr. Kidder's suggestion that aluminum conductors might be used in place of copper is interesting. Aside from possible reduction in conductor losses, there may, in fact, be conditions where the use of aluminum conductors will result in a lower cost installation, as, for example, where the diameter of the pipe used with copper conductors is sufficiently large to accommodate aluminum conductors having a conductance about equal to that of the copper conductors.

The matter of reduction of pipe losses is touched on by Mr. Kidder and Mr. Wiseman. Of course, a suitable nonmetallic pipe, if such were available, would be the most satisfactory answer. A metallic, nonmagnetic pipe would be a satisfactory answer only if the resistivity of the pipe material is extremely high. It is evident from equation 14 that, within the assumptions used, the loss in nonmagnetic pipe is proportional to the thickness of the pipe and inversely proportional to its resistivity. For magnetic pipe actual thickness is replaced by the "depth of penetration," which is of the order of 5 to 10 per cent of the thickness. Taking into account the multiplying factor of 2.6 for magnetic pipe, the resistivity of nonmagnetic pipe must be of the order of 4 to 8 times that of steel, that is, 30 to 60 times that of copper, to produce the same loss as steel pipe, assuming the same wall thickness. To obtain lower losses than with steel pipe, the resistivity of the nonmagnetic pipe would have to be still higher. It may be expected, however, that the use of nonmagnetic pipe will reduce the conductor and shield losses somewhat.

Regarding the losses in magnetic pipe, it should be pointed out that the losses are high primarily because the conductance is high and not because the pipe is magnetic. The common impression, reflected in Mr. Wiseman's comment, is that the way to reduce losses in magnetic pipe is to reduce the permeability. On the contrary, the evidence is that reducing the permeability will increase the losses. Thus, the two lines of attack are to increase the resistivity and to increase the permeability. From the data in Table II of the paper it appears that, with the currents used in the tests, the permeability of the 8-inch pipe is about 50 per cent higher than that of the 6-inch pipe, yet the pipe loss factor is about 15 per cent lower for the 8-inch pipe than for the 6-inch pipe, in spite of the fact that the resistivity of the 8-inch pipe is 10 per cent lower. Similarly, the data in Mr. Wiseman's Table XIII indicate lower permeability and higher resistivity for the steel pipe than for the various conduits, but the loss data indicate higher losses for the steel pipe. Deduction from equation 14 leads to the same conclusion, bearing in mind that, for magnetic pipe, t must be replaced by "depth of penetration," which is inversely proportional to the square root of the permeability.

The excellent agreement between pipe losses as calculated by the simple formulas used by Mr. Wiseman and as calculated by equation 15 is interesting and suggests that for purposes of rough approximation, simple approximations of some of the other equations in the paper also may be found useful.

In Table IV of the discussion Mr. Wiseman gives loss data on four additional cables. It is assumed that these were tested with close triangular configuration. It is to be regretted that construction details have not been given, as these would add greatly to the value of the data.

In Figure 2 of the discussion, Mr. Kidder points out the large spread of effective conductance with conductors of the same size. The reduced effective conductance was produced in most cases by low resistance shields but in one case perhaps by low contact resistance in the strand. It should be noted that Mr. Kidder's comparison of different constructions on the basis of conductance alone, as derived from over-all a-c/d-c ratio, is an oversimplification of the actual design problem and one that could readily lead to erroneous conclusions concerning carrying capacity. In addition to the over-all a-c/d-c ratio one must of necessity give proper weight to the point in the thermal circuit at which the various losses are generated. It is obvious, for example, that a given degree of extra loss developed in the conductors will produce more rise in temperature than an equal amount of extra loss originating in the shielding assembly or in the pipe.

Again referring to Mr. Kidder's Figure 2, it will be noted that our samples 2*A* and 2*B* fall below the line drawn from the approximate calculated losses as given in Table XV of the paper. The reason for this is that the actual conductor diameters, and hence the conductor separations, were somewhat smaller than for conventional concentric strand, which were used in calculating Tables XV and XVI, resulting in lower actual than calculated losses. The loss values as given in Tables XV and XVI were intended to be conservative.

2.5	0.295	0.595	4.0	0.584	1.160

Mr. Buller points out various discrepancies between measured and computed values. The measured skin effect values as given in the original Table III of the preprint of this paper are indeed somewhat higher than the corresponding values in Table XI. However, the skin effect values given in Table III are based on measured resistances at temperatures somewhat lower than 30 degrees centigrade, whereas in Table XI they are based on calculated resistances at a specific temperature. Since there is no particular point in showing the values of skin effect to the third decimal, as was originally done, the values in the revised Table III are shown only to the second decimal.

The discrepancies in shield proximity losses pointed out by Mr. Buller must be attributed to sample variability. These losses constitute a minor part of the total losses and are entirely negligible for the more common cable constructions. Moreover, the results obtained from the equations, as given, appear to be conservative for most cases. Until further data show it to be desirable, there does not appear to be much need for revision of these equations or any of the others given in the paper.

Regarding the value of 6.0 for K, which was indicated for one case of strand with two insulated segments, this was obtained on one specific sample which had a low resistance path between the two bare segments, produced by a lapped bronze binder, and in which the contact resistance between individual wires might be expected to be low by reason of the fact that it received no drying treatment at all. As also pointed out in the paper, the data for a segmental cable reported by Mr. Wiseman show a K value of 5.4. However, it was not intended to convey the impression that all segmental strand with two insulated segments have so high a K factor. Indeed, tests performed since the presentation of the paper have shown that a K factor of 3.8 applies not only to strand having three insulated segments, but also to strand having two insulated segments, provided that the cable with two insulated segments is dried with access of air for part of the time and the conductor binder consists of a bronze tape, intercalated with a paper tape, or is of some other construction having sufficiently high resistance.

We agree with Mr. Buller on the desirability of supporting the K_1 factor for loss in magnetic pipe with extensive data. However, we believe the data given in Table VII are sufficient for a good start in that direction. Perhaps other investigators will supply additional data.

Mr. Neher suggests that a better method of approach toward the evaluation of extra a-c losses is on the basis of apparent resistance increment rather than ratio of a-c to d-c resistance. From the operating man's standpoint his suggestion has much merit. However, the use of the ratio lends itself more readily to the accumulation and evaluation of laboratory data. We believe that this is largely a matter of personal preference, as is also the choice between the K factor as used in the paper and the F factor suggested by Mr. Neher, and the use of conductor resistance instead of conductor size in the pipe loss formula.

Regarding Mr. Neher's suggestion of evaluating skin and proximity effect in air together instead of separately, we believe that separate evaluation has certain advantages, especially because in segmental conductors different K factors apply for the two, K being about 4.5 for skin effect and 3.8 for proximity effect.

It is interesting to note that Mr. Neher has found from available data more or less definite multiplying factors between excess a-c conductor loss in pipe and in air.

Empirical equation 7 given in the paper was an attempt to correlate all available data. Perhaps there is not adequate justification to go beyond establishing constants for the various broad conditions as Mr. Neher has done.

In compliance with Mr. Del Mar's suggestion, there are given in Table V of the discussion, $G(x)$ and $H(x)$ values for the range of x values required in the present connection for equations 5 and 6. These were taken from Table I of reference 4 of the paper.

Self-Saturation in Magnetic Amplifiers

W. J. DORNHOEFER
ASSOCIATE AIEE

THE PURPOSE of this paper is to describe self-saturation in magnetic amplifier circuits and to propose a simplified but approximate method of calculating the performance of this type of circuit. To illustrate the simplified method, the calculated performance for a particular case is compared with the measured performance.

Saturable Reactors

The literature is replete with references to the elementary magnetic amplifiers known as saturable reactors.[1] A saturable reactor, as is known, is a device having an a-c impedance which can be adjusted by means of d-c premagnetization. Simple saturable reactors, in general, are of slightly larger size than 2-winding transformers of the same kilovolt-ampere rating. They are commonly made in one of two styles—3-legged or 4-legged. In the 3-legged reactor, the a-c windings embrace the outer legs of a shell-type transformer structure, while the control, or d-c winding, embraces the inner leg. The a-c windings are so connected in series or in parallel that the fundamental magnetic flux path is through the outer legs and yokes, giving no fundamental component of power-frequency voltage in the control winding. In the 4-legged reactor, a-c windings are wound on each of the two inner legs, while the d-c winding embraces both. In this case also, no fundamental component of power-frequency voltage is induced in the control winding. With respect to static performance, the two constructions yield reactors with similar characteristics. While differences exist between them with respect to leakage flux conditions and even-harmonic pick-up in the control coil, the 3- and 4-legged reactors operate in much the same way.

The reactance of the a-c windings is adjusted by varying the value of d-c premagnetization in the a-c magnetic path, by passing direct current through the control winding. The reactance is an inverse function of the control current, so that it is maximum at zero direct current and falls to relatively low values at high values of premagnetization. Obtaining optimum utilization of the reactor structure involves supplying a premagnetization with the d-c winding at least equal to the peak magnetomotive force developed by the a-c coils plus the amount necessary to saturate the magnetic circuit of the reactor. Generally, the d-c increment is from 25 to 100 ampere-turns per inch of mean magnetic path. As the result of the excess of d-c over a-c ampere-turns, saturable reactors usually are made with more of the window space devoted to control-winding copper than to power-winding copper. For this reason, a reactor of a given rating is generally slightly larger in size than its analogous 2-winding transformer.

However, assuming that the same window space will be used by both the a-c and d-c windings gives a simplified and not-inaccurate idea of saturable reactor sizes and amplifications. For example, if the copper losses of a moderate sized transformer constitute approximately 2 per cent of the rating of the transformer, the copper losses of each winding are the equivalent of 1 per cent of the rating. The a-c winding of a reactor resembles the secondary winding of the transformer in that the current and voltage ratings are equivalent if each has the same amount of iron and secondary copper. For equal d-c and a-c window space and ampere-turns, copper losses in the d-c and a-c reactor windings are equal, both being 1 per cent of the reactor rating for this example. Thus the effective power gain realized through decoupling the d-c winding from the a-c winding is of the order of 100. In practice, because of the use of more than 50 per cent of the window by the d-c coil, gains of approximately 250 can be realized in 50-kva saturable reactors, while gains of approximately 50 are obtained in 2-kva reactors. Of course, the gains mentioned are realized partly at the expense of apparatus efficiency; that is, a larger amount of iron and copper must be provided in the reactor than in a transformer of equivalent rating.

Saturable Reactor Limitations

The simple saturable reactors described have several limitations. The control windings require a great many turns of small wire, in which the induced voltages become extremely high if one of the two a-c coils becomes inoperative. Because of the many turns used in the d-c coils, all of which link the entire magnetic circuit, the time delay (or effective time constant) of the d-c coil is generally long. The delay is reduced if the d-c winding is controlled from a high-resistance source or if resistance is inserted in series with the control coil. This method of reducing the time constant of the control circuit is not economical of control power, and the gain in dynamic response is accomplished only at the expense of the power amplification of the saturable-reactor circuit.

Reactors with Feedback

In simple saturable reactors, a considerable portion of the control power is required to equilibrate the peak a-c magnetomotive force. By making use of feedback or compensation, this portion may be reduced. The use of feedback permits the same range of control of the output as is available in simple reactors. The d-c coil supplies only the magneto-

Paper 49-140, recommended by the AIEE Electronics and Basic Sciences Committees, and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer General Meeting, Swampscott, Mass., June 20-24, 1949. Manuscript submitted December 1, 1948; made available for printing May 16, 1949.

W. J. Dornhoefer is with the Vickers Electric Division of Vickers, Incorporated, St. Louis, Missouri.

motive force required to saturate the magnetic circuit of the reactor, while the feed-back means supplies sufficient magnetomotive force to equilibrate that of the a-c coils. Several investigators have reported on a method of feedback known as self-excitation or external feedback.[2,3,4] External feed-back circuits are shown in Figures 1 and 2. In these circuits, the alternating current flowing in the main windings is rectified and caused to flow in additional windings on the reactors in such a way that in one reactor the d-c magnetomotive force assists the a-c magnetomotive force at a given instant; while in the other, the d-c ampere-turns oppose the a-c ampere-turns. Of course, on the succeeding alternation of current, the assistance and opposition alter in sense, so that, at any instant, either one or the other of the a-c windings exerts no net magnetomotive force on the core, providing the feedback winding turns are made approximately equal to the a-c winding turns. As a result, saturation of the magnetic core material by means of the d-c control winding can be accomplished by supplying only sufficient magnetomotive force to saturate the magnetic circuit.

External feed-back circuits offer considerable improvement in sensitivity over the simple saturable-reactor arrangement. It is possible, by adjusting the turns in the feed-back winding, to compensate exactly, to over-compensate, or to under-compensate for the power-winding magnetomotive force. Overcompensation corresponds to feedback reactors having feedback turn ratios of greater than unity. It has the effect of reducing the control ampere-turns required by the reactor and accentuating nonlinearities in the output versus d-c premagnetization, or transfer, curve. Under-compensation gives opposite effects.

Several important considerations which enter the design and evaluation of such circuits involve the precision of the equilibrium which can be obtained between the magnetomotive forces of the a-c and feed-back windings. In general, it is not only desirable but absolutely necessary to reduce the leakage flux between the a-c power winding and the feed-back winding to a minimum. This is often done by winding both at the same time, that is, two-in-hand. Moreover, it is necessary to be certain that the current conversion ratio of the rectifier does not change. This, of course, means that back-current leakage in the rectifier must be minimized. The considerations involved in equilibrating the feed-back and a-c winding magnetomotive forces are particularly important with reactors using high quality magnetic materials in gapless magnetic circuits.

θ_f = angular argument at which firing occurs, radians

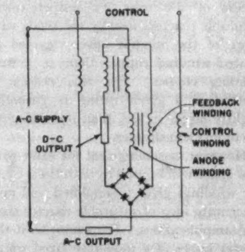

Figure 2. Circuit diagram of a d-c premagnetized reactor having external feedback and series connection of a-c windings

One investigator[5] has reported a 4 to 1 change in the output versus input characteristics of a magnetic amplifier using external feedback when the turns in the feed-back winding were changed from 100 per cent of the power winding turns to 100.1 per cent of power-winding turns.

These results, as might be expected, were found using high quality core material with a gapless structure. Variations of magnetic amplifier characteristics to be expected with reactor core structures built up of conventional *E-I*, *E-E*, or *F*-type laminations, and the adverse effect of slight unbalances in feed-back turns, would not be as great.

Self-Saturation

Another method of balancing the power-winding magnetomotive force involves the use of self-saturation of the type found in the circuit given in schematic form in Figure 3.[6,7]

The schematic circuit drawing of Figure 3, while not that of a practical self-saturating magnetic amplifier, will serve to illustrate the form of feedback which is the principal topic of this discussion. In this circuit an electric valve is connected in series with the power winding of a reactor. Ideally, the current flowing in the power winding is pulsating and unidirectional, and causes pulsating, unidirectional magnetic flux in the core of the reactor, which flux never falls below a minimum value. This value depends on the maximum flux density and magnetizing force achieved during the forward alternation of supply voltage and positive pulsation of anode-winding current. It depends also on the magnetomotive force of the control winding.

In order that the effect upon the output of premagnetization supplied by the control winding may be appreciated, a

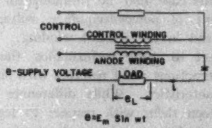

Figure 3. Circuit diagram of the basic half-wave magnetic amplifier with self-saturation

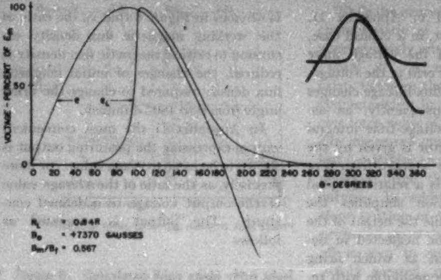

Figure 4. Calculated wave form, see Appendix I, of output voltage of a half-wave magnetic amplifier circuit and oscillogram for corresponding conditions

$B_m/B_f=0.57$	$B_m/B_f=0.57$
$R_L/R=1.0$	$R_L/R=0.94$

typical reactor with self-saturation is analyzed in Appendix I. Briefly, this appendix treats a half-wave magnetic amplifier, with a sufficiently high impedance connected in control circuit so that the voltage induced in the control winding causes no fundamental-frequency current. (In the case of the practical magnetic amplifier circuits, the induced voltage of fundamental frequency which appears in each control coil is balanced by an equal voltage in another coil; these are so connected that no fundamental voltage appears at the control-circuit terminals.) It is shown in Appendix I that the calculated output-voltage wave resembles the output of a gas-filled grid-controlled electronic tube. See Figure 4. The output-voltage wave form contains a portion with very great slope, which is associated with "firing" of the magnetic amplifier. The time at which firing occurs depends on the magnetomotive force H_0 of the control winding, and in particular, upon the initial magnetic flux density B_0 associated with this magnetomotive force. For purposes of comparison, an oscillogram of the measured output-voltage wave form for the same conditions and values used for the calculation is shown also in Figure 4. A recalculated output-voltage wave form, which is more nearly in accordance with the test conditions of the oscillogram, is shown in Figure 5.

The labor involved in the step-by-step calculations of Appendix I makes it an inconvenient method either for gaining a general understanding of the circuit or for predicting performance.

$B_m/B_f=0.57$	$B_m/B_f=0.57$
$R_L/R=0.94$	$R_L/R=0.94$

Effect of Control Premagnetization

The effect of control premagnetization upon the output can be seen in the oscillograms of Figures 6 and 7. As the values of H_0 and B_0 are adjusted, the point of firing varies along the angular time base from 180 degrees towards 0 degrees. Before firing, virtually all the supply voltage is absorbed as a voltage-time integral (flux-linkage change) by the coil. After firing the core is saturated, and almost all of the supply voltage appears on the load resistor. This is particularly evident in the oscillograms of Figure 6. Corresponding oscillograms showing magnetic conditions in the core are given in Figure 7.

The operation of the circuit can be considered in a simplified way as being of this nature:

> The anode winding is capable of developing a large electromotive force due to magnetic flux changes with small changes and small values of anode current, since the reactor for which the oscillograms are shown has a high-permeability gapless core structure. Consequently, from $t=0$, when the supply voltage becomes positive with positive slope, until some later time, all of the supply voltage appears across the anode winding of the reactor, which may be thought of as absorbing a voltage-time integral. The absorption of a voltage-time integral by the reactor must be associated with a change of magnetic flux in the reactor core. When the change of flux from the initial value is such that the magnetic flux density reaches a certain critical value B_f, firing occurs. At firing, the reactor no longer can readily change its flux linkages, and the current increases abruptly from a small value to a value sufficient so that the iR drop is approximately equal to the supply voltage. Figure 4 shows that the iR drop is actually in excess of the supply voltage by the small amount associated with the low rate of discharge of the reactor flux linkages as the magnetic flux is dropping below its maximum value.

The B versus $H(B)$ oscillograms of Figure 7 will serve to illustrate the operation of the self-saturating magnetic amplifier circuit somewhat more clearly. They represent the operating minor hysteresis loops existing in the circuit for which the supply-voltage and load-voltage oscillograms of Figure 6 were taken. The oscillograms are shown in the same order as in Figure 6 from minimum output to a maximum output. The outputs are given in a convenient form developed in Appendix II.

Effect of Hysteresis

The oscillograms of Figure 7 give an insight into the principal factor involved in control of the output. When the minimum flux density, which is the flux density in the core at the time of the axis-crossing with positive slope of the supply voltage, is adjusted to a minimum value ($B_0=-5,300$ gausses in Figure 7), the excursion of flux density associated with the supply voltage, the anode turns, and the core area, is not sufficient to cause saturation of the reactor, so that the anode current remains at a small value corresponding to a normal alternating exciting current of the reactor. As the initial flux density B_0 is adjusted upward, firing occurs. As B_0 is increased, firing occurs earlier in time phase and results in larger peak and average values of a-c magnetizing force H_t and output voltage. From these oscillograms, it is evident that the fundamental consideration involved in controlling a self-saturating reactor output is the matter of adjusting the initial magnetic flux density at the time of the axis-crossing with positive slope of the supply voltage. This also is evident from the analysis of Appendix I.

Also shown there is the manner in which the magnetomotive force of the control winding establishes the value of B_0. The relation giving initial magnetic flux density in terms of H_0 is determined as the upper branch of the hysteresis loop.

It is shown that the peak magnetizing forces reached are greatly in excess of the coercive force of the material. As a matter of fact, the peak magnetizing forces in the particular circuit for which the oscillograms of Figure 7 are shown, amount to more than 1,000 times the coercive force of the material. Consequently, operation corresponding to the decay of flux is on the upper branch of the first, second, and third quadrant hysteresis loop, with maximum induction at saturation.

As a result of the saturation caused by the anode current on each half cycle, during the next half cycle when no anode current flows, the magnetic core is in a condition somewhere along the upper branch of the hysteresis loop. Thus, control is obtained along this portion of the magnetization curve, rather than on the normal magnetization curve.

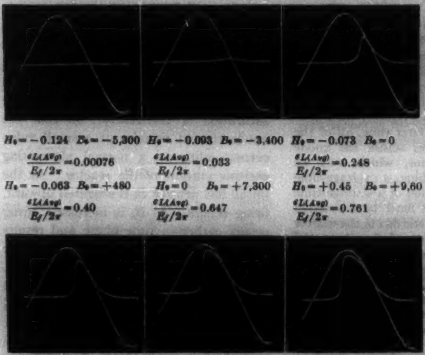
Output, Firing Angle

A method of calculation giving the approximate firing angle and output voltage is developed in Appendix II. It is shown there that, in a typical case, the prefiring skirt of the voltage wave represents about 3 per cent of the voltage-time integral causing flux-linkage changes in the reactor. Consequently, an assumption that the voltage-time integral absorbed by the reactor is given by the integral of the supply voltage from zero to the firing instant is a relatively good one. This assumption simplifies the analysis greatly. While the height of the prefiring skirt may be neglected in determining the instant at which firing occurs, it may not be negligible with respect to the output. Furthermore, it is assumed that all of the circuit resistance is in the load, and that no extraneous effects, such as eddy-current shielding occur. What the assumptions amount to then is this: Before firing all of the supply voltage appears across the coil, while after firing all of the supply voltage appears across the load. This is obviously a rather naive assumption, but it will be seen that the results are in fair agreement with the approximations developed on this basis. Following Appendix II, the firing angle is given by

$$\theta_f = \cos^{-1}\left(\frac{B_m+B_0-B_f}{B_m}\right) \quad 0\leq\theta_f\leq\pi \qquad (11)$$

Figure 6. Oscillograms of supply voltage and load voltage of the half-wave magnetic amplifier shown in Figure 3. For increased values of B_0, "firing"—the abrupt rise in output voltage—occurs at earlier instants; that is, at smaller firing angles

$B_m/B_f=0.57$ $R_L/R=0.94$



This relation giving the firing angle is plotted in Figure 8. Several features of the relation are of interest. In the first place, if the working magnetic flux density B_m exceeds the critical magnetic flux density at which firing occurs, then regardless of the value of B_0, firing cannot be prevented. Consequently, one of the elementary principles of self-saturating magnetic amplifiers is operation of the reactor core material at magnetic flux densities below the critical value. It also is obvious in Figure 8 that as the ratio of the working magnetic flux density excursion to critical magnetic flux density is reduced, the changes of initial magnetic flux density required to change the firing angle from 0 to 180° diminish.

In Appendix II the most convenient way of expressing the postfiring output is shown to be as an average value—or more precisely, as the ratio of the average value of the output voltage to a defined constant. The output is expressed as follows

$$\frac{e_{L(avg)}\Big|_{\theta_f}^{\pi}}{E_f/2\pi}=\frac{2B_m}{B}+\frac{B_0}{B_f}-1$$

$$-1\leq\frac{B_0}{B_f}\leq+1 \qquad (14)$$

A chart of this relation is shown in Figure 9, which is the so-called transfer or static characteristic of an ideal half-wave magnetic amplifier circuit. The postfiring output ratio is plotted as the ordinate while the ratio of initial to critical magnetic flux density is shown as abscissa. The transfer curves in these co-ordinate systems are straight lines. The effect of changing the ratio of working magnetic flux density excursion to the critical magnetic flux density value is shown for several values of the ratio.

Experimental Results

idealizing assumptions of Appendixes I and II, a magnetic amplifier circuit using a core as shown in Figure 10 was constructed and tested. Oscillograms of supply voltage, load voltage, and B versus $H(B)$ have been shown for stated conditions in Figures 6 and 7. Evaluation of oscillograms, several of which are given in Figure 6, serve to determine the firing angle, yielding the experimental points shown in Figure 12. Data and the calculated firing angle curve are for $B_m/B_f=0.57$. Correspondence between the measured values of firing angle and the theoretical values is no better than fair, because the oscillograms of Figure 6 were taken on small 35-millimeter film, making the firing angles rather difficult to measure accurately.

A calculated transfer characteristic, with the initial premagnetization in terms of a magnetizing force rather than a ratio of initial to critical magnetic flux density, is shown in Figure 13. The abscissas are given in oersteds, while the ordinate is shown as the output factor of equation 14. As a result of the shape of the hysteresis loop, the straight lines of Figure 9 are reflected in Figure 13 as shown, with large slope in the vicinity of the coercive force value of the magnetizing force and with small slope in the vicinity of the flat portions of the hysteresis loop of Figure 11.

A set of measured transfer characteristics for a half-wave magnetic amplifier circuit of the sort which has been under discussion is shown in Figure 14. The ordinate has been reduced to the normalized units of equation 14, and the abscissas have been calculated on the basis of the known control magnetomotive force and the arithmetic mean length of magnetic path in the core.

While the general shape of the measured characteristic of Figure 14 corresponds approximately with the calculated shape, Figure 13, a noticeable discrepancy exists between the slopes of the transfer characteristics in the region of the coercive force value of the magnetic intensity. The measured curves show a great deal less sensitivity to changes of control magnetizing force than do the calculated curves. In addition, if the maximum slope portion of the measured curves is projected upon the axis of abscissas, cut-off is seen to occur in the vicinity of −0.12 oersted, rather than the −0.08 oersted value predicted by the calculations.

Several explanations of this departure from expected behavior are possible. Two are considered most likely. They are: eddy-current shielding of the laminated core structure and consequent broadening of the hysteresis loop; and the effect of the distributed parameters of the magnetic circuit of the test core. It is shown in Appendix II that the reason for the discrepancy between the calculated and measured results probably is concerned with the radial depth of the toroidal magnetic core. Careful consideration of the conditions in the core during the time when control is obtained, that is, during the negative alternation of the supply voltage, indicates that for complete cut-off, the initial flux density in the extreme magnetic path must be reduced to the cut-off value. However, the cut-off value of initial flux density for the inner portion of the lamination is reached considerably earlier because of the shorter magnetic path. If the measured transfer curve for $B_m/B_f=0.57$ is compared with the calculated transfer curve based on the mean length of magnetic path, 21.9 centimeters, curves *A* and *C* of Figure 15 result. If, now, the calculation is extended to include the effect of the extreme length of magnetic path, curve *B* of Figure 15 results. It will be seen that curve *B* is more nearly in agreement with the measured curve in the vicinity of the linear portion of the characteristic than is the curve calculated on the basis of mean length of magnetic path, curve *A*. While no further work has been done to determine the exact effect of the radial depth of the magnetic core and to confirm what may be inferred from Figure 15, it is felt that the radial depth consideration offers a reasonable explanation of the departure of the calculation, using only the mean length of magnetic path, from the measured performance.

Initial Induction, B_0

The value of magnetic flux density B_0 in the core at the start of the forward alternation of supply voltage plays a major role in determining the subsequent values of maximum, rms, and average output current and voltage. The changes in value of B_0 which result in changes of

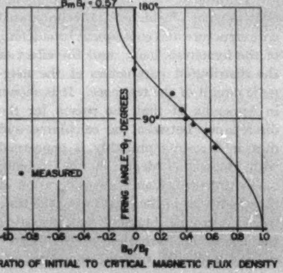
output may occur as a result of the operation of several factors, of which the control current, anode current, operating hysteresis loop, and magnetic circuit configuration are most obvious. It is desired, of course, that changes in output result only from changes of the control current.

The control characteristics of a magnetic amplifier employing self-saturation are dependent to a great degree upon the characteristic of the rectifier which is employed, particularly the reverse characteristic. As an example, in the circuit under discussion here, the peak anode magnetizing force amounted to approximately 112 oersteds. Reverse current leakage permitted by the rectifier of only 1 per cent would cause an anode demagnetizing force during the negative alternation of the supply voltage of 1.12 oersteds, which is almost ten times the value needed in the control winding for full control. With leaky rectifiers, the control winding would have to provide the control shown in Figures 13 and 14, plus sufficient magnetizing force to compensate for leakage of the rectifiers. Consequently, rectifiers for use in magnetic amplifier circuits must have high values of reverse resistance, particularly where high-permeability cores with gapless construction are employed.

Figure 12. Measured and calculated firing angles of half-wave magnetic amplifier circuit consisting of a reactor with core as shown in Figure 10 and magnetization curve as shown in Figure 11. The measured values of firing angle are from oscillograms, several of which are shown in Figure 6

$B_m/B_f = 0.57$



The rectifiers used most commonly in the magnetic amplifier practice are of the metallic type. Metallic rectifiers, of course, have limited values of inverse resistance, which means simply that the reverse current associated with rectifier leakage causes an increase of control ampere-turns required for a given change of magnetic amplifier output. The effect of leakage currents in magnetic amplifiers is an upward shift of the control characteristics of the amplifier, by an amount which depends on the leakage. If the inverse resistance of the rectifiers were constant, the amount of shift would, of course, be proportional to the supply voltage. This general effect is seen in the family of magnetic amplifier transfer curves shown in Figure 16. These transfer curves were taken with a magnetic core material of even higher permeability than the medium-nickel-iron alloy for which the curves thus far have been shown, and with particularly unsuitable rectifiers, in order to bring out the effect of reverse current. For small applied voltages, leakage in the rectifier causes little shift of the characteristic. As the ratio to working flux density to critical flux density is increased, that is, as the supply voltage is increased, the reverse current increases, causing the upper curves of the family to shift into the positive control region. The amount of the shift in control is proportional to the magnetomotive forces developed by the reverse current in the anode winding. In general, the desired characteristics of metallic rectifiers for magnetic amplifier circuits are both high inverse resistance to minimize the leakage, and low forward drop. In order to minimize the number of series rectifier cells which must be employed in the stack, it also is desirable that the allowable working voltage per cell be as high as possible. Good practice dictates, for instance, that, with commercial selenium rectifier plates normally rated at 18 volts rms per cell, working voltages for magnetic amplifier circuits be of the order of 8 to 12 volts per cell, which means about 10 series plates per leg for

Figure 15. Calculated and measured average output voltage of a half-wave magnetic amplifier circuit as a function of the control magnetizing force, with the radial depth of the core of Figure 10 taken into consideration

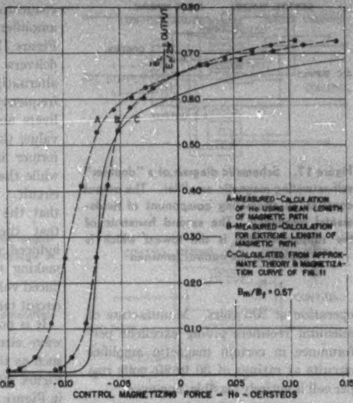


Figure 16 (lower right). Family of transfer characteristics of a magnetic amplifier with 80 per cent nickel-iron reactor cores and metallic rectifiers. The shift of similar portions of the characteristics toward the right is due to reverse current leakage of the rectifiers as the working magnetic flux density (B_m/B_f) and applied voltage increase

operation at 100 volts. Manufacture of selenium rectifiers giving excellent performance in certain magnetic amplifier circuits at ratings of 30 to 40 volts rms per cell is entirely feasible, however.

Control Means

The half-wave self-saturating magnetic amplifier circuit which has been discussed thus far is susceptible to control by any of several means. The basic means is the adjustment of the value of initial flux density during the nonconducting portion of the cycle, that is, during the reverse alternation of supply voltage. Various means may be employed to adjust this value of initial flux density. The most obvious, of course, is premagnetization by means of continuous direct current. However, other means are equally feasible. Control of the initial flux density by means of synchronous alternating current, adjustable either in amplitude or in phase, may be employed. Control by means of amplitude variation of a synchronous alternating current also is feasible in many cases. In addition, control may be achieved by changing the reverse current in the anode winding during the nonconducting portion of the cycle by shunting adjustable impedance elements across the anode winding or the rectifier.

Magnetic Amplifier Circuits

The half-wave magnetic amplifier circuit which has been employed for analysis and study thus far is of little practical value, principally because a component of electromotive force of fundamental frequency appears at the control-circuit terminals. In practical magnetic amplifier circuits this control-circuit component of fundamental electromotive force must be minimized or eliminated. This is done in single-phase circuits by connecting a second half-wave magnetic amplifier circuit to the first, as shown in Figure 17 or 18. The circuit of Figure 17 delivers an output which contains an alternating component of fundamental frequency, while that of Figure 18 delivers an output which has an average value, that is, a direct component. The former is called the "doubler" circuit, while the latter is called the "full-wave" circuit. It will be noted in these figures that the control coils are so connected that the fundamental components of induced voltage in the coils are opposed, making the lowest harmonic of the induced voltage that appears at the control-circuit terminals the second.

It is possible to connect the basic half-wave circuit in polyphase arrangements such as the 3-phase wye circuit shown in Figure 19, the 6-phase star circuit shown in Figure 20, or the 3-phase bridge circuit shown in Figure 21. In general, the polyphase circuits are used where particularly fast response is required and where output ripple requirements are difficult to meet with the single-phase circuits.

The magnetic amplifier circuits of Figure 22 are basically self-saturating magnetic amplifier circuits, in which added external feedback has been employed for the purpose of reducing the control change required for a prescribed output change. The object generally is overcoming the effect of leakage in the rectifiers. The turns associated with the added feed-back winding are few, being of the order of 1 or 2 per cent of the main-winding turns.

External Feedback and Self-Saturation

From the discussions thus far it is apparent that under ideal conditions the static performance of the circuits using external feedback, Figures 1 and 2, and of the self-saturating circuits are virtually identical, since the purpose of the feedback in both cases is to balance the magnetomotive force of the anode windings and thus permit control of the magnetic amplifier output with an amount of signal power equal to that required for saturation of the magnetic core material. A recent analysis has indicated excellent correspondence both for calculated and for measured static performance of the two circuits for the case of built-up laminated cores with air gaps.[12]

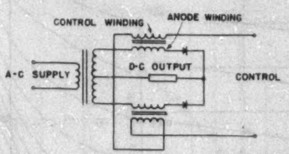

Figure 18. Schematic diagram of a "full-wave" self-saturating magnetic amplifier. The output contains a direct component. The second harmonic of the a-c supply is the lowest which is present at the control terminals

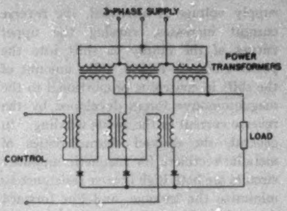

Figure 19. Schematic diagram of a "3-phase half-wave" self-saturating magnetic amplifier. The output contains a direct component. The third harmonic of the supply voltage is the lowest which is present at the control terminals

In both circuits, the characteristics of the rectifiers are quite important, if not critical. In the self-saturating circuit, limited reverse resistance of the rectifiers causes back-current demagnetization of the core during the nonconducting half cycle, with consequent loss of amplification. In the Buchold circuit, Figure 1, a change of current conversion ratio of the rectifiers, resulting from back-current leakage of the nonoperating rectifiers, has much the same effect. In the magnetic amplifier circuit using external feedback, leakage flux between the feed-back winding and the anode winding plays a major role in determining the effectiveness of the feedback. No such consideration exists in the self-saturating circuit.

A further relation between the two circuits is found from consideration of the apparatus utilization. Considering two magnetic amplifiers, one with the Buchold circuit of Figure 2 and one with the self-saturating circuit of Figure 17, in which the magnetic core structures are identical and in which the applied voltages are the same, only 1/2 the a-c winding turns are required for the former as compared with, the latter. Since, in the Buchold circuit, the feed-back turns equal the a-c turns the same total turns and wire size are employed. In the self-saturating circuit, the full load current flows in the full reactor turns 1/2 the time. In the Buchold circuit, the full load current flows in all

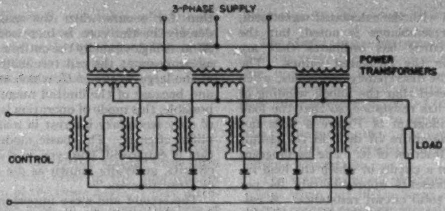

Figure 20 (above). Schematic diagram of a "6-phase diametrical" self-saturating magnetic amplifier. The output contains a direct component. The sixth harmonic of the supply voltage is the lowest which is present at the control terminals

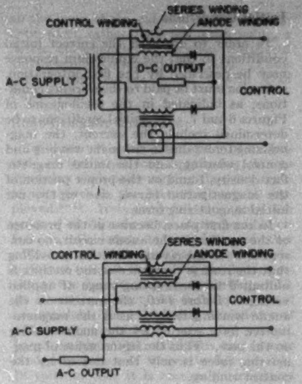

Figure 22 (right). Schematic diagrams of doubler and full-wave self-saturating magnetic amplifiers with added external feedback to compensate for rectifier leakage current

windings during the entire cycle, and the power dissipation in the circuit with external feedback is twice that in the self-saturating circuit. Conversely, for the same temperature rise, the output of the Buchold circuit must be limited to 50 per cent of that allowable in the self-saturating circuit using the same weight of copper and iron. To reach the same output with the Buchold circuit with operation on the same voltage, the copper section must be approximately doubled. Thus, twice the window area will be required for the circuit using external feedback. If a square window and the same stack is assumed, doubling the window means an increase of approximately 41 per cent in the mean length of the magnetic path and weight of core material, as well as the 100 per cent increase of copper weight.

Appendix I

Circuit Relations, Assumptions

The half-wave magnetic amplifier circuit shown in Figure 3 is analyzed here, and an example is calculated for the core shape shown in Figure 10, with core material characteristics as given in Figure 11. The differential equation applying to the circuit is solved by step-by-step numerical integration for a particular set of operating conditions and circuit parameters, in order to find the waveform of the voltage appearing across the load resistor e_L.

The differential equation describing the voltage relations in the circuit of Figure 3 is

$$e = N\frac{d\phi}{dt}\times 10^{-8}+iR+e_R \qquad (1)$$

If the applied voltage is sinusoidal

$$E_m \sin \omega t = N\frac{d\phi}{dt}\times 10^{-8}+iR+e_R$$

$$E_m \sin \omega t - e_R = N\frac{d\phi}{dt}\times 10^{-8}+iR \qquad (2)$$

If $E_m >> e_r$, it is approximately true that

$$E_m \sin \omega t = N\frac{d\phi}{dt}\times 10^{-8}+iR$$

$$d\phi = \frac{(E_m \sin \omega t - iR)}{N}dt\times 10^{8} \qquad (3)$$

For the present, it is assumed that the distributed parameters of the magnetic circuit may be lumped to an effective area A and an arithmetical mean magnetic path length l.

Further, it is assumed that the impedance of the control circuit is of large enough value to suppress harmonic currents in the control circuit. This assumption is permissible and, in fact, required because in practice, with high-permeability cores and circuit connections as in Figures 17 through 21, harmonic currents flowing in the control circuit have limited effect on the static performance. In the circuits mentioned, no fundamental component of supply-frequency voltage is found at the control-circuit terminals. In addition, resistance usually is added in the control circuit to reduce the amplifier time constant. As a result, the only alternating current superimposed on the control current is a higher harmonic of small amplitude. To make the calculated response of the half-wave circuit resemble conditions actually found in the conventional self-saturating amplifier, it will be assumed that the control circuit impedance is sufficient to suppress all but the signal current. As a result, the magnetizing forces of the anode winding and of the control winding are sufficient to give the total magnetic intensity

$$H(B) = H_0 + H_i$$

$$H_i = \frac{0.4\pi Ni}{l}$$

$$d\phi = A\,dB$$

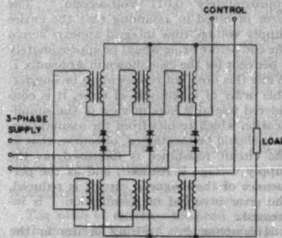

Figure 21. Schematic diagram of a 3-phase bridge self-saturating magnetic amplifier. The output contains a direct component. The sixth harmonic of the supply voltage is the lowest which is present at the control terminals

Then from equation 3

$$dB = \left(\frac{E_m \sin \omega t}{NA} - \frac{H_i l R}{0.4\pi N^2 A}\right)dt\times 10^{8} \qquad (4)$$

Since $H(B)$ enters the relation giving the differential flux change, analytical solution of equation 4 is possible only if $H(B)$ can be expressed as an explicit function of B. While an approach involving use of an analytical expression of $H(B)$ in terms of B is feasible, it becomes burdensome when the relation is radically nonlinear, causing the higher-order terms of the series expansion to have substantial coefficients. In particular, in this case the response of the circuit to a sinusoidal input voltage includes a waveform which is extremely nonsinusoidal, containing at one point a slope which approaches a finite discontinuity. Consequently, the higher-order terms of an analytical expression for $H(B)$ would have to be considered, should an analytical solution be required. It is more convenient for the purpose of this appendix to solve the differential equation, which has numerical coefficients if the circuit parameters and operating conditions are given, by direct numerical integration, employing the magnetization curve of Figure 11 for data. As in any numerical integration process, the increments of angular argument must be small, particularly in regions of sharp curvature of the characteristic curve, if the requirements implicit in the numerical method are to be satisfied.

Initial Conditions

In order to establish the correct initial conditions so that the equilibrium response may be described by the first integration, attention must be paid to the working conditions, as indicated in the oscillograms of Figures 6 and 7. The initial conditions to be determined include the current, the magnetizing forces due to the main winding and control winding, and the initial magnetic flux density, found on the proper portion of the magnetization curve, due to the net initial magnetizing force.

In the first place, because of the presence of the rectifier in the anode circuit, no current flows in the reverse direction, providing that the reverse resistance of the rectifier is unlimited in the working range of applied voltage. Before $t=0$, the current in the anode winding is zero, as is the magnetomotive force exerted by the main winding on the core. Thus the initial value of magnetizing force is only that caused by the control winding.

Secondly, in order to determine the initial magnetic flux density, it is necessary to note in the oscillograms that the forward current during the positive alternation of the supply voltage causes magnetic intensities greatly in excess of the coercivity of the material. This may be verified by observing in the B versus $H(B)$ oscillograms of Figure 7 that the right-hand portion of the magnetization curve is essentially flat, indicating that the core material becomes thoroughly saturated during the forward alternation of the supply voltage. Following saturation, the decaying value of anode-winding magnetizing force approaches zero along the upper branch of the hysteresis loop, indicating that during the succeeding negative alternation, the magnetic condition of the core is defined by that branch of the loop. The value of initial magnetic flux density B_0 then may be found, for a given value of initial premagnetization H_0 exerted by the control winding, by referring to the upper branch of the hysteresis loop.

Sample Wave Form Calculation

Following determination of the initial conditions, numerical integration according to equation 4 is carried out. A particular set of values has been chosen for illustration; a calculated load voltage wave form is shown in Figure 4. The illustrative values are:

$E_m=141.4$ volts
$l=21.9$ centimeters
$R=50.3$ ohms
$N=650$ turns
$\omega=377$ radians per second
$A=6.45$ square centimeters
$H_0=0$ oersteds
$B_0=7{,}300$ gausses
Magnetization data as given in Figure 11

The working equation is

$$dB=\left(E_m\sin\theta-\frac{H_i lR}{0.4\pi N}\right)\frac{d\theta}{\omega NA}\times 10^8 \qquad (5)$$

The calculated wave form of the total iR drop in the anode circuit is shown in Figure 4. Also shown is an oscillogram of e_L taken in a half-wave circuit with values as enumerated, core as in Figure 10, and magnetization curve as in Figure 11. When this is compared with the calculated wave form, a general resemblance is noted, but the calculated curve has ordinates that are greater than the measured values. The reason for the discrepancy is obvious, when it is considered that the anode winding of the reactor has resistance, so that the load voltage oscillogram of Figure 4 does not represent the entire iR drop in the circuit but only a fraction of it. The oscillogram was taken in a circuit in which the load resistance represents approximately 94 per cent of the total circuit resistance. A calculated wave form of load voltage with this factor considered is shown in Figure 5, together with another oscillogram of the measured wave form with the same conditions.

Appendix II

While the method of numerical integration illustrated in Appendix I serves to predict approximately the wave form of the output voltage, from which the effective and average values may be found, it is not convenient to use in predicting the static performance characteristic of the amplifier, principally because of the labor involved. It is the purpose of this appendix to point out how the performance curves may be simply approximated, and to indicate the magnitude of the errors introduced by the simplifying assumptions made in the course of the approximation.

Firing Angle

Assumption 1. Firing of a half-wave self-saturating magnetic amplifier circuit employing a high-permeability gapless core occurs abruptly enough so that the iR drop before firing may be neglected in determining the angular argument at which firing occurs.

In evaluating this assumption, it is revealing to consider the calculated response of the circuit given in Appendix I. In Figure 5, firing occurs at approximately 90 degrees. The voltage-time integral (flux-linkage change) absorbed by the anode winding during the prefiring interval is 0.375 volt-second, less the value of voltage-time integral associated with the voltage drop in the circuit resistance during that interval—approximately 0.011 volt-second. The error involved in assuming that the entire supply voltage-time integral appears across the coil before firing would be approximately 3 per cent for the case shown in Appendix I. While this does not represent an inconsiderable order of magnitude of error, it is considered tolerable here in view of the simplification which results from the assumption.

It should be mentioned, of course, that as the circuit resistance is increased, as the supply voltage is reduced, and as the permeance of the magnetic circuit is reduced, the error involved in Assumption 1 is increased.

Assumption 2. Firing occurs in the mode shown in Appendix I. This limitation rejects one of the two possible modes of firing. The rejected mode obtains when the core is premagnetized beyond negative saturation in a negative direction ($B_0<-B_f$). If this condition exists, then, following $t=0$, the entire supply voltage appears initially as a drop on the circuit resistance. Firing in a reverse sense from that illustrated thus far occurs when the magnetic flux density in the core is increased to $-B_f$. After firing, virtually the entire supply voltage appears at the coil terminals. Because of the large values of H_0 which are required and because of the limited range of control possible, this mode of operation is at present of only secondary interest in magnetic amplifier circuits. This basic mode of operation is employed, however, in d-c metering circuits, generally known as d-c converters or "transformers."[18]

The second and more important mode of firing, for magnetic amplifiers at any rate, is the type illustrated in Appendix I. The restriction $-B_f\leq B_0\leq +B_f$ is sufficient to include this mode and exclude the d-c "transformer" mode.

On the basis of these assumptions and those of Appendix I, a simple relation for the firing angle may be set down, following equation 3. Since the prefiring skirt is neglected, and $d\phi=AdB$, equation 3 becomes

$$dB=\frac{E_m\sin\omega t}{NA}dt\times 10^8 \qquad (6)$$

$$B=B_0+\int\frac{E_m\sin\omega t}{NA}dt\times 10^8 \qquad (7)$$

Firing occurs when the instantaneous magnetic flux density reaches the critical value B_f

$$B_f=B_0+\int_0^{t_f}\frac{E_m\sin\omega t}{NA}dt\times 10^8 \qquad (8)$$

$$B_f-B_0=\frac{E_m\times 10^8}{\omega NA}(1-\cos\omega t_f)$$

$$\theta_f=\cos^{-1}\left(1-\frac{(B_f-B_0)\omega NA}{E_m\times 10^8}\right) \qquad (9)$$

where

$$\theta_f=\omega\times t_f$$

But the maximum value of flux density associated with the supply voltage is

$$B_m=\frac{E_m\times 10^8}{\omega NA}$$

so that

$$\theta_f=\cos^{-1}\left(1-\frac{B_f-B_0}{B_m}\right) \qquad (10)$$

The values of the angular argument at which firing occurs are given by equation 10. Restrictions of the value of θ_f exist and should be recognized. Because of the rectifier

$$\theta_f\leq\pi$$

Because of the limitation of Assumption 2 that is, $-B_f\leq B_0\leq +B_f$

$$\theta_f\geq 0$$

Thus a complete statement giving the firing angle in convenient form is

$$\theta_f=\cos^{-1}\left(\frac{B_m+B_0-B_f}{B_m}\right);\ 0\leq\theta_f\leq\pi \qquad (11)$$

It is most convenient to plot equation 11 by showing θ_f as a function of B_0/B_f with B_m/B_f as parameter. This is done in Figure 8. As an experimental check, a set of load-voltage oscillograms, several of which are shown in Figure 6, were taken with the circuit parameters and conditions as in Appendix I and with the core of Figure 10. The calculated firing-angle curve, together with the experimental points, are shown in Figure 12.

Output

Assumption 3. While ignoring the prefiring skirt of the output-voltage wave form introduces small error in the approximate calculation of the firing angle, it may introduce serious error in the approximation of output.

As is obvious in the first two oscillograms of Figure 6, for values of B_0 near cut-off there may be measurable output, even though sharp firing never occurs. As an approximation to be evaluated later by comparison of calculated and measured static characteristic or transfer curves, let the alternating exciting current corresponding to the value of working flux density B_m be added to the postfiring output to represent the contribution of the prefiring skirt. Comparison of transfer curves will indicate whether this approximation is justified.

To find the output current and voltage after firing, it is convenient to express the output voltage as an integrated average value. To be consistent with the assumptions made thus far, if all the circuit resistance is in the load

$$e_L=E_m \sin\theta;\ \theta_f\leq\theta\leq\pi$$

Expressing the postfiring output voltage as an integrated average value

$$e_{L(Avg)}\Big|_{\theta_f}^{\pi}=\frac{1}{2\pi}\int_{\theta_f}^{\pi}E_m \sin\theta d\theta \tag{12}$$

$$e_{L(Avg)}\Big|_{\theta_f}^{\pi}=\frac{E_m}{2\pi}(1+\cos\theta_f) \tag{13}$$

From equation 11

$$e_{L(Avg)}\Big|_{\theta_f}^{\pi}=\frac{E_m}{2\pi}\left(1+\frac{B_m+B_0-B_f}{B_m}\right)$$

A more convenient form of output relation results if a critical maximum voltage is defined as

$$E_f=\omega NAB_f\times10^{-8}$$

Thus

$$e_{L(Avg)}\Big|_{\theta_f}^{\pi}=\frac{\omega NA}{2\pi}(2B_m+B_0-B_f)\times10^{-8}$$

And finally

$$\frac{e_{L(Avg)}\Big|_{\theta_f}^{\pi}}{E_f/2\pi}=\frac{2B_m}{B_f}+\frac{B_0}{B_f}-1 \tag{14}$$

Since

$$0\leq\theta_f\leq\pi$$

The output is restricted

$$0\leq\frac{e_{L(Avg)}\Big|_{\theta_f}^{\pi}}{E_f/2\pi}\leq\frac{2E_m}{E_f}$$

The ideal postfiring average output of the half-wave magnetic amplifier circuit is shown in Figure 9 as a function of B_0/B_f, with B_m/B_f as parameter.

Transfer Characteristic

The ideal transfer characteristic of Figure 9 shows several features of magnetic amplifier operation. For values of maximum working magnetic flux density in excess of the critical value $B_m/B_f>1.0$, the output can never be reduced to zero, regardless of the premagnetization. For lower values of B_m/B_f, the characteristic shows both cut-off and saturation.

The transfer curves of Figure 9 are more useful when put in the form of an output versus control magnetic intensity chart with B_m/B_f as parameter, as in Figure 13.

The calculated transfer curves are shown with the H_0 magnetic intensity value found from the upper branch of the hysteresis loop of Figure 11, and with several values of B_m/B_f as parameter. It should be noted that the calculation gives $e_{L(Avg)}/(E_f/2\pi)$ as a function of H_0 without regard for the particular values of circuit parameters. Further, the alternating exciting currents are added to the postfiring output to account for the effect of the prefiring skirt, which is particularly evident near cut-off and below.

A set of measured transfer curves for magnetic and electric circuit parameters as in Appendix I and Figure 10, is shown in Figure 14. In order to simplify comparison, the output has been reduced to the general form given in equation 14. Values of control H_0 given in Figure 14 were calculated from the data by making use of the known control winding turns and current and an arithmetic mean value of magnetic path length (21.9 centimeters).

The general shapes of the calculated and measured curves show certain resemblances. The calculated effects of saturation for positive values of H_0 are seen to occur in the measured curves, and the nature of the effect of the working value of flux density (B_m/B_f) on the value of H_0 for cut-off is seen to be predicted correctly by the calculation. There is one notable difference between the calculated and measured curves—the slope and location of the linear, sensitive portion of the transfer curve.

In order that this discrepancy between the calculated approximate performance may be seen more clearly, the measured transfer curve for $B_m/B_f=0.57$ and a transfer curve for that value calculated by making use of the approximations are shown in Figure 15. The measured transfer curve *A* is plotted as before, with H_0 found by the calculation from the known magnetomotive force and the arithmetic mean magnetic path length. It is obvious that the linear portion corresponds neither in slope nor in location with the calculated curve.

Possible explanations of the discrepancy involve the effect of distributed magnetic circuit of test core and eddy-current shielding of the core laminations.

MAGNETIC CIRCUIT

The ratio of extreme to mean magnetic path length of the core structure of Figure 10 is 1.36, while the ratio of longest to shortest path length is 2.14. In view of these values, it might be questioned whether calculations of the sort thus far outlined, which are based on a lumped magnetic circuit with a fixed path length, properly apply to such a core.

It is of interest to note that if the experimental data are reduced to fundamental units on the basis of the extreme length of magnetic path, rather than the mean value, a better correspondence between calculated and measured performance is found. (Compare transfer curves *B* and *C* with *A* of Figure 15.)

EDDY-CURRENT SHIELDING

In order to evaluate the order of magnitude of hysteresis loop broadening due to operation with time-varying flux, the techniques given in the literature may be employed.[9–11] It is intended that only the order of magnitude of the worst possible effect be calculated, to determine whether eddy-current demagnetization might be sufficient to cause the shift of the linear portion of the transfer curve noted in Figure 15. As a matter of fact, the techniques which are available for calculating the effects of eddy-current shielding are, in general, based on sinusoidal conditions and low or moderate values of magnetic flux density. In spite of this, it is reasonable to expect that at least the order of magnitude of the effect can be predicted in this case.

In order to determine the maximum broadening to be expected, for the 47.5 per cent nickel-iron alloy used, take:

$\rho=51\times10^{-6}$ ohm-centimeters
$\mu=50{,}000$ centimeter-gram-second electromagnetic units
$f=60$ cycles per second
$a=0.0084$ centimeter–half lamination thickness

Then, following the procedure of reference 10:

$$\frac{L}{L_0}=\frac{s}{2a}\frac{\sinh\left(\frac{2a}{s}\right)+\sin\left(\frac{2a}{s}\right)}{\cosh\left(\frac{2a}{s}\right)+\cos\left(\frac{2a}{s}\right)}$$

where s is the skin depth and is given by

$$s=\frac{5{,}030}{\sqrt{\frac{\mu f}{\rho}}}=0.0208 \text{ centimeter}$$

The ratio of lamination thickness to skin depth is

$$\frac{2a}{s}=0.804$$

Solving

$$\frac{L}{L_0}=0.96$$

At this frequency, the greatest broadening of the hysteresis loop which might be expected is of the order of 4 per cent, a value insufficient to resolve the discrepancy between curves *A* and *C* of Figure 15. Consequently, it is inferred that the effect is probably due principally to the radial depth of the test core.

Discussion

L. A. Finzi, D. W. VerPlanck, D. C. Beaumariage (Carnegie Institute of Technology, Pittsburgh, Pa.):

Mr. Dornhoefer is to be congratulated for an analysis of a half-wave magnetic amplifier circuit which is very interesting and thought provoking, and which appears to throw further light on the behavior of practically useful circuits having two or more elements. It would be of interest to know more about how the author uses his results as obtained for the single-element case in predicting the performance of actual amplifiers.

Comparing Mr. Dornhoefer's analysis with that given by the writers in a paper presented at the same session,[1] it is seen that there are two basic differences in the underlying assumptions:

1. Mr. Dornhoefer assumes that his control circuit has infinite impedance to harmonic currents, while the writers' analysis[1] takes the opposite extreme and assumes that harmonic currents may circulate freely there.

In other terms the writers have dealt with a case which has been called unconstrained or natural magnetization[2] while Mr. Dornhoefer assumes totally constrained conditions.

2. Mr. Dornhoefer treats a case where the magnetization curve has a relatively sharp knee and then becomes essentially horizontal permitting no further increase in flux. The writers, on the other hand, treat the case of a core which never reaches complete saturation.

It appears thus that by other combinations of the alternatives under each of the preceding statements, one may have two additional extreme types of treatment, making a total of four. It is conceivable that practical conditions might arise making anyone of these four the best approach.

S. B. Cohen (Sperry Gyroscope Company, Great Neck, N. Y.): The assumptions used for the determination of θ_f are valid for most of the magnetic materials used, including cores made up of EI^-, EE^-, or F-type laminations. We have been able to reproduce Figure 12 of the paper with about the same degree of correlation using EI and EE cores.

The determination of the output (voltage or current) is, however, a more difficult problem and depends upon the assumptions used and the type of core construction and material.

In Appendix I, the step-by-step solution of the differential equation 5 of the paper yields a current or voltage output across the load as is shown in Figures 4 and 5 of the paper. The angle at which conduction ceases can be called the conduction angle θ_t. In Figure 4 of the paper the conduction angle is about 260 degrees. This conduction angle is a function of the material and core structure if the core is made up of EI- or EE-type laminations. However, in Appendix II, the angle of conduction was assumed to be 180 degrees. This assumption is valid if:

1. Most of the resistance of the circuit is assumed to be in the load.
2. The material and core used present an extremely low effective impedance when saturated, that is, the B-H characteristic is almost a horizontal line after saturation.

These assumptions are essentially valid for the particular examples in Appendix II. However, in those cases where core structure (that is, EI-type), and material do not have the characteristic as mentioned previously in assumption 2 (for example, silicon iron for higher power work), and where the load resistance is comparable to the rectifier impedance, which may be the case when matching for maximum power into the load, the assumptions are not quite valid.

If equation 2 of the paper were solved for the current

$$E_m \sin \omega t = N\frac{d\phi}{dt}10^{-8} + iR_T + e_R$$

or

$$E_m \sin \omega t = L\frac{di}{dt} + iR_T + e_R$$

where

$L(di/dt)$ is the equivalent of $N(d\phi/dt)10^{-8}$

The value of L is the equivalent value of inductance of the core when saturated, because we are interested in the current during the conduction period. If assumption 2 were valid, then L would be zero.

For some value of θ_f; say $\theta_f = 0$ degrees, the solution of equation 2

$$i(t) = I_m\left[\sin(\theta-\omega t) + \frac{\sigma}{\cos\theta} - \left(\sin\theta + \frac{\sigma}{\cos\theta}\right)\epsilon^{\frac{-R_T}{\omega L}\omega t}\right]$$

where

$$I_m = \frac{E_m}{\sqrt{R_T^2 + (\omega L)^2}}$$

$$\theta = \tan^{-1}\frac{\omega L}{R_T}$$

$$\sigma = \frac{e_R}{E_m}$$

to solve for θ_t, set $i(t) = 0$

$$\sin(\theta-\theta_t) + \frac{\sigma}{\cos\theta} = \left(\sin\theta + \frac{\sigma}{\cos\theta}\right)\epsilon^{\frac{-R_T}{\omega L}\theta}$$

This equation is solved empirically for θ_t.

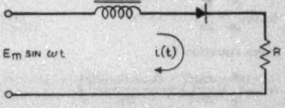

Figure 1. Self-saturable magnetic amplifier circuit

The solution for θ_t as a function of $\omega L/R_T$ is plotted in Figure 2 of this discussion with σ as a parameter. From this plot, we can see that for $\sigma = 0$ assuming $e_R = 0$ and rectifier is constant resistance lumped in R_T, the conduction angle is 180 degrees as $\omega L/R_T$ approaches zero. It is possible to obtain large values of θ_t if $\omega L/R_T$ increases as is shown. It also is interesting to note that for finite values of σ, the conduction angle can be less than 180 degrees.

The use of material in cores other than those mentioned in assumption 2 introduces finite values of $\omega L/R_T$ which can be large enough to yield values of θ_t, which are appreciably higher than 180 degrees. The errors introduced in the calculation of power output by using 180 degrees instead of the θ_t from Figure 2 of the discussion may be as high as 25 per cent in some cases.

Since in many applications power is the primary interest, a plot of power as a function of $\omega L/R_T$ is shown in Figure 3 of the discussion for various values of σ. If E_m were 37 volts (26 volts rms) and the drop across a typical rectifier were 2 volts, then $\sigma = 2/37 = 0.054$. This would mean a loss

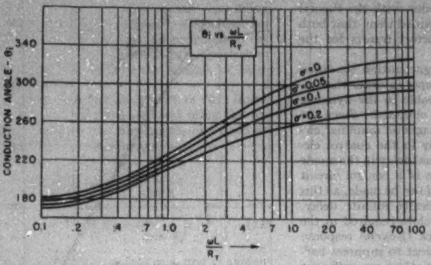

Figure 2. Conduction angle (θ_i) as a function of $\omega L/R_T$

of about 20 per cent in power at optimum conditions.

It is interesting to note that the optimum value of $\omega L/R_T$ for maximum power is about 2.4 for $\sigma = 0$. This means that $R_T = \omega L/2.4$ for maximum transfer of power to R_T.

Another set of curves, Figure 4 of the discussion, indicates the effect of the rectifier resistance in the power transferred to the load. These curves were calculated for $\sigma = 0$, but assuming the rectifier to be a resistance equal to R_T. This means that e_R actually exists and varies, but according to the method used in the setting up of the equation, we have $\sigma = 0$. As can be seen from these curves, the point of maximum power varies with variations in λ.

The type of calculation and curves presented in this discussion can be used to obtain a step-by-step determination of the transfer curves in the self-saturable amplifier. We have used the curves drawn for various values of θ_f, σ, and θ_i to obtain end design figures for various types of amplifier applications.

The experimental results yield fairly close correlations using the design values so obtained. The use of *EI*-type laminations yield inferior results with respect to gain per unit time constant as compared to the solid stamping or ribbon-wound type cores. However, the maximum power obtained is almost the same for a given size core, and the stability obtained as far as reproducibility is concerned is quite good.

In many applications, the lower performance can be tolerated, but the reproducibility is very desirable.

It may be of interest, therefore, to include in the theory of calculating procedure methods for handling cores which do not exhibit the ideal characteristics, and also conditions in which the forward characteristics of the rectifiers used are not negligible in comparison to the load and anode winding.

H. F. Storm (General Electric Company, Schenectady, New York): In his very interesting paper Mr. Dornhoefer presents several transfer characteristics of magnetic amplifiers, such as those shown in Figures 13–16 of the paper. These characteristics demonstrate the performance of magnetic amplifiers in the region of high gain; that is, between the lower and the upper right knee, but they do not indicate the trend beyond the two knees. In Appendix II, Mr. Dornhoefer mentions correctly that the operation beyond the lower knee is related to the mode of operation of d-c metering circuits, and then lists references 13 and 14. While Mr. Dornhoefer's paper deals with regenerative circuits, the aforementioned reference does not include such circuits; hence the reader may remain in doubt as to the performance of magnetic amplifiers beyond the lower knee. Inspecting Figures 13–16 of Mr. Dornhoefer's paper, the reader may conclude that for large negative control currents the transfer characteristics approach zero output current. This, however, is not so; on application of large negative control currents the load current again increases as shown in Figures 5 and 6 of the discussion. It is the object of the following discussion to describe the transfer characteristic beyond the region shown in Mr. Dornhoefer's paper.

Figure 5 of the discussion demonstrates a transfer characteristic of a magnetic amplifier which Mr. Dornhoefer calls "full-wave" self-saturating connection, Figure 18 of the paper; more specifically, it relates to a circuit where the impedance of the source of control current is small in comparison with the resistance of the control winding. In that region of the transfer characteristic which is located to the right of the lower knee, a change of control current I_c in a negative direction will cause a reduction of the load current I_L, both currents being measured in average values. However, if the control current is made more negative than the value corresponding to the lower knee, that is, in this case, more negative than —5 milliamperes, the load current again increases. In order to demonstrate the full range of negative control currents, Figure 6 of the discussion utilizes a much larger scale for the control-current scale. It can be seen from this figure that the load current I_L first increases almost linearly with negatively increasing control current I_c, and finally approaches a horizontal asymptote at the same level as for very large positive control current (Figure 5 of the discussion). It is an important conclusion that increasing the negative control current causes a reduction of load current when operating to the right of the lower knee, but an increase of load current when operating to the left of the lower knee.

In automatic-control and regulator engineering an error signal often is used to excite the control winding of a magnetic amplifier. This error signal normally operates on the steep section of the transfer characteristic, that is, to the right of the lower knee. The magnetic amplifier usually is connected into the regulated system in such manner as to reduce the error signal and thus tends to keep the regulated quantity constant. If now a large disturbance occurs in the regulated system, the error signal suddenly may become so large as to operate on that part of the transfer characteristic which is to the left of the lower knee. Hence, the load current instead of becoming smaller actually may increase instead and thus produce a still larger error signal. As a result

Figure 3. Power coefficient (ξ) as a function of $\omega L/R_T$ with σ as a parameter

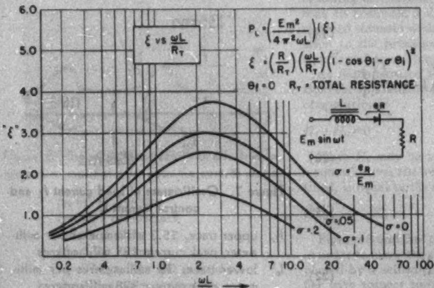

Figure 4. Power coefficient (ξ) as a function of $\omega L/R_T$ with λ as a parameter

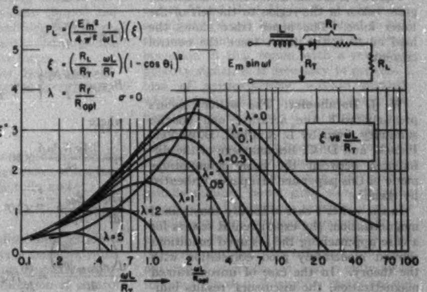

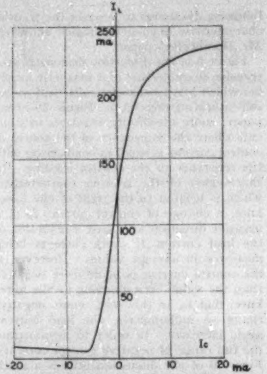

Figure 5. Transfer characteristic of magnetic amplifier in the region of highest gain

the system will no longer operate as a regulator but may drive itself into a ceiling condition. Such occurrence obviously should be avoided, and in order to evaluate the possibility of loss of control, it is necessary to know the transfer characteristic to the left of the lower knee.

There are theoretical reasons why this transfer characteristic should approach a straight line throughout a considerable range of negative control currents as demonstrated by Figure 6 of the discussion. While space does not permit dwelling on these reasons in this discussion, the resulting equation for the straight line approximation can be stated simply.

$$I_L = -I_c \frac{N_c}{N_L}$$

where I_L is the average current in the load resistor (see Figure 18 of the paper), I_c the average current in the control winding, N_c the number of turns of the control winding, and N_L the number of turns of the anode winding.

This equation gives a good approximation when the reactor material is operated at magnetic flux densities at or below the critical value, as defined in Mr. Dornhoefer's paper.

Figure 7 of the discussion shows an oscillogram taken in the region to the left of the lower knee. The upper trace shows the load current, the lower trace the control current.

W. J. Dornhoefer: The writer concurs precisely with the accurate and concise summary given by L. A. Finzi, D. W. VerPlanck, and D. C. Beaumariage of the differences between the basic assumptions made in this paper and in a paper presented by them.[1]

In the writer's case of totally constrained magnetization, the experimental results for a case approaching the assumed conditions showed moderately good correlation with the theory. In the case of unconstrained magnetization, the discussors' results indicated excellent correlation with the theory. It may be taken for granted then, that both approaches lead to correct results for the assumed conditions.

The constrained magnetization condition was assumed in this paper in order that results ultimately applicable to the dynamic performance might be obtained. Since the time delay found in magnetic amplifier circuits resides principally in the control circuit, with a small residual delay in the anode circuit, the assumption of a control circuit lacking resistance could not be made, as this would involve theoretically infinite delay. While the resistance values required in the control circuit for quick (1-cycle) response are generally not sufficient to suppress harmonic currents entirely, they are sufficient to make the assumption quite reasonable.

The dependence of the transient response of saturable reactors upon the control circuit resistance was given in an unpublished paper by Mr. Finzi, Mr. VerPlanck and Mr. Beaumariage. In this paper, the assumption of zero control circuit impedance would have led to trivial results and could therefore not be made as it was before. Rather, the significant time-delay factor was shown to be of the nature

$$\tau_s = \frac{2N_1A}{\mu R_1 I_1 \infty}$$

where

N_1 = control turns
A = core area
R_1 = proportional to control circuit resistance
μ = magnetization curve-fitting argument
$I_1\infty$ = ultimate value of control circuit current

A similar relation can be shown for the self-saturating case with small changes of output for which an effective permeability can be defined. Following equation 14 of the paper

$$\frac{d\left(e_{L(avg)}\Big|_{\theta_f}^{\pi}\right)}{dt} = \frac{d}{dt}\left\{\frac{\omega NA}{2\pi}(2B_m + B_0 - B_f) \times 10^{-8}\right\} \qquad (15)$$

$$\frac{d\left(e_{L(avg)}\Big|_{\theta_f}^{\pi}\right)}{dt} = fNA\frac{dB_0}{dt} \times 10^{-8} \qquad (16)$$

$$i_0 = i_{00} + \frac{E_{dc}}{R_1}\left(1 - \epsilon^{-\frac{t}{\tau_1}}\right) \qquad (17)$$

$$B_0 = \mu\frac{0.4\pi N_1}{l}i_0 \qquad (18)$$

$$B_0 = \mu\frac{0.4\pi N_1}{l}\left\{i_{00} + \frac{dc}{R_1}\left(1 - \epsilon^{-\frac{t}{\tau_1}}\right)\right\} \qquad (19)$$

where

$$\tau_1 = \frac{0.4\pi N_1^2 \mu A}{lR_1} \times 10^{-8} \qquad (20)$$

$$\frac{dB_0}{dt} = \frac{E_{dc}}{N_1A}\epsilon^{-\frac{t}{\tau_1}} \times 10^8 \qquad (21)$$

$$\frac{d\left(e_{L(avg)}\Big|_{\theta_f}^{\pi}\right)}{dt} = \frac{N}{N_1}fE_{dc}\epsilon^{-\frac{t}{\tau_1}} \qquad (22)$$

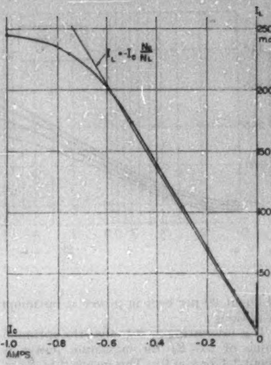

Figure 6. Transfer characteristic of magnetic amplifier for negative control currents

Anode winding: 592 turns each, control winding: 200 turns

where

i_{00} = initial control current
E_{dc} = amplitude of step-function input voltage change
R_1 = control circuit resistance
τ_1 = control circuit time constant (approximate)
N_1 = control winding turns

and the remainder of the nomenclature is as given in the paper.

Again, as in the results cited previously, the control circuit resistance is an important quantity insofar as transient response is concerned. The values of R_1 for fast response were felt to be such that the case of zero harmonic currents in the control circuit would be the more generally useful one, particularly where transient response might be an important consideration.

Mr. Cohen's discussion, giving the calculation of self-saturating magnetic amplifier output for the completely saturated condition, is a useful contribution to the calculation methods for this type of circuit. The assumption of a constant post-firing inductance adds to the difficulty of literal solution but leads to extremely interesting results.

Essentially the method given by Mr.

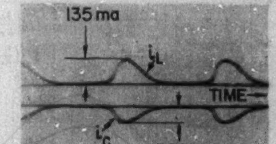

Figure 7. Oscillogram of load current I_L and control current I_c

I_L: upper trace, 15.3 milliamperes per millimeter, peak current 135 milliamperes
I_c: lower trace, 75 milliamperes per millimeter, peak current 398 milliamperes

Cohen involves an assumption resembling Mr. Boyajian's "2-zone" magnetization curve,[2] as does the method proposed in the paper. In Mr. Cohen's case, particular attention was paid to the second, or saturated, zone.

Adapting equations 21–24 of Mr. Boyajian's paper to this case, and using the nomenclature of the discussion, one finds an expression for the current

$$i_{(t)}=I_m\left\{\sin(\omega t-\theta)-\frac{\sigma}{\cos\theta}+\left(\sin\theta+\frac{\sigma}{\cos\theta}\right)\epsilon^{-\frac{R_T}{L}}\right\}\qquad(23)$$

As Mr. Boyajian points out, and is evident in his Figures 5 and 6, the exponential decay of current after the axis-crossing with negative slope of the supply voltage is principally a zone *1*, or unsaturated, variation. Examination of a numerical integration schedule, or of Figures 6 and 7 of the paper, seems to confirm this. Of course, by his assumption $\theta_f=0$, Mr. Cohen has excluded all unsaturated operation of the reactor and has given a useful calculation method for the saturated output. It would be interesting to see a general "2-zone" treatment in which θ_f was not so restricted.

The treatment of the effect of nonideal rectifiers on the saturated output also is of considerable interest, particularly in view of the indication given in Figure 2 of the discussion that assumption 3 of the paper would be very poor for large values of $\omega L/R_T$ and small values of σ.

The discussion of the shape of the transfer characteristic of a self-saturating magnetic amplifier in the range of extreme negative premagnetization beyond the cutoff point, or lower knee, which Mr. Storm has prepared, represents an important addition to the material contained in the paper. The mode of firing involved in operation in this region has been described[3,4] and is presented briefly: Due to saturation, the reactor cannot initially change its flux linkages and thus can introduce no voltage drop in the anode circuit. As a result, the anode current, following the axis-crossing with positive slope of the supply voltage, increases sinusoidally, as in a resistive circuit, until it has reached a value sufficient so that the anode magnetomotive force equilibrates the premagnetizing magnetomotive force. When this condition prevails, the reactor core becomes unsaturated and is capable of developing an inductive voltage in the anode winding. This voltage assumes a value so that the load current is constant and gives rise to an anode-winding magnetomotive force which remains equal to the premagnetizing magnetomotive force during the remainder of the alternation. Similar events occur in the other anode circuit during the following alternation, causing the load current to resemble a drastically clipped and rectified sinusoid with amplitude directly related to the premagnetization through the equality of magnetomotive forces.

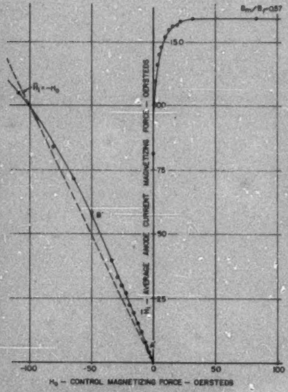

Figure 8. Transfer characteristic of a full-wave magnetic amplifier over extreme control range

E_m=141.4 volts
l=20.1 centimeters
R=40.5 ohms
N=1,200 turns
ω=377 radians per second
A=3.5 square centimeters

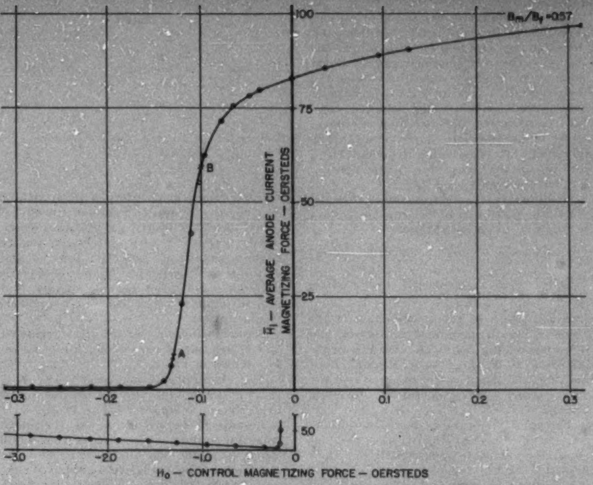

Figure 9. Transfer characteristics of a full-wave magnetic amplifier over normal control range

As demonstrated in Mr. Storm's discussion, the fundamental relation for this mode of operation is

$$H_t+H_o=0\qquad(15)$$

Since H_t may be taken approximately as a square wave, the average value, when rectified, is equal to the amplitude, and

$$H_{t(avg)}=-H_o\qquad(16)$$

Figures 8 and 9 of the discussion are given in order to show the extreme anisotropy displayed by a self-saturating magnetic amplifier with respect to the direction of control premagnetization on opposite sides of cut-off. They are quite similar to Figures 5 and 6 of Mr. Storm's discussion, referring as they do to the same type of circuit, and are presented to illustrate the effect of extreme negative premagnetization for conditions similar to those of the illustrative example given in the paper. While the saturable-core reactors employed were not identical with those described in Appendix I, they were gapless and consisted of the same material, and had magnetization data similar to Figure 11.

The increase of output on either side of the cut-off point, which has been pointed out by Mr. Storm with particular reference to automatic control and regulator applications, is evident in Figure 8 of the discussion, and in the inset of Figure 9 of the discussion. In order to determine the importance of the loss of signal polarity sense in automatic control work, the orders of magnitude of the effects must be considered. As an example, in regulator applications, it is generally desirable to limit the range of operation of the amplifier to that portion of the characteristic between points A and B of Figure 9, at which the sensitivity (slope) has been reduced to half the maximum value. In order to permit operation in this region with a reversible polarity signal, it is necessary to provide a bias of approximately −0.115 oersted; while a single polarity signal would require a negative bias of at least 0.130 oersted.

Generally, the use of extreme negative bias on a single-ended amplifier, together with signal values of commensurate magnitude, is to be avoided, since the result is usually reduced power gain, slow dynamic response, and inordinate sensitivity of the amplifier to supply voltage changes. In the case of a push-pull amplifier, bias is used only to establish the balanced quiescent outputs of each channel, and is quite small in value. Push-pull amplifier stages are not subject to complete loss of signal polarity sense under extreme signal conditions, and are thus excluded from this discussion. Actually, the only amplifiers subject to this possibility are single-ended units operating with reversible polarity signals or with extreme negative bias. In addition, good practice dictates the matching of impedances of intermediate stages of multistage amplifiers, thus precluding the possibility of loss of polarity sense due to overdrive in any but the lowest-level stage.

In automatic control work, then, the cases where the possibility of loss of polarity sense is a significant consideration are:

1. Input stage, single-ended, reversible polarity signal.

2. Input stage, single-ended, extreme single-polarity signal and bias values.

Examination of the co-ordinates of the points A and B mentioned previously, and of corresponding points (A′ and B′) on the left portion of the transfer characteristic indicates the signal values required to cause "transformer" mode operation, shown in Table I.

The sensitivity ratio is seen to be $(49.4-5.5)/(0.130-0.0098)=1{,}370$, while the bias ratio, or permissible signal overdrive ratio is $5.5/0.13=42.3$.

As indicated above and in Figures 8 and 9 of the discussion, a difference of sensitivity of more than three orders of magnitude is seen to exist on opposite sides of cut-off. A signal overdrive of at least 40 times is evidently permissible as well. As the quality of the magnetic core material is lowered, and as the reverse resistance of the rectifiers is reduced, these ratios become smaller, and may ultimately reach values that would be troublesome.

Table I

Point	$H_{i(avg)}$ Oersteds	H_0 Oersteds
A	6.75	− 0.130
A′	6.75	− 5.5
B	57.8	− 0.098
B′	57.8	−49.4

Table II

Point	I_1 Milliamperes	I_0 Milliamperes
A	25	− 3.9
A′	25	− 75
B	180	+ 2.5
B′	180	−550

Similar ratios for Mr. Storm's Figures 1 and 2, locating the operating limits as before shown in Table II.

The sensitivity ratio equals $(550-25)/(2.5+3.9)=82$, and the permissible signal overdrive ratio equals $75/3.9=19.2$.

Providing the overdrive on the input stage due to the extreme value of a push-pull signal, or of the bias alone with zero value of extreme single-polarity signal, is maintained within the foregoing limits (20 to 40), little difficulty is encountered with the "transformer" mode of operation. It also should be mentioned that optimum gain and speed of response considerations in high-performance regulators and servomechanisms generally limit the operating levels to maximum overdrive ratios of approximately three to five.

Automatic Grounding and Air-Break Switches for Protection of Transformer Stations

E. A. RICKER
MEMBER AIEE

A COMBINATION of an automatic-grounding switch with an automatic-opening air-break switch can be used as a substitute for a 110-kv circuit breaker. Although customers, who are supplied from a small transformer station tapped to a 110-kv line, would have an occasional interruption in service, they are receiving electric energy at a lower rate per kilowatt-hour because of the lower capital cost of the transformer station. Since each 110-kv circuit breaker requires two isolating disconnecting switches, the capital reduction for each combination of automatic switches is almost equal to the installed cost of one circuit breaker. With proper installation and maintenance, the switches will give reliable protection for small transformer stations.

The following paragraphs give a discussion of the preferred station diagrams, ways of mounting these switches, and reviews of experience since 1930 with several types of automatic switches operated by spring and motor-driven mechanisms amounting to a total of 260 switch years. The favorable operating experience with automatic disconnecting switches has resulted in their adaptation for use in other parts of transformer stations.

Sequence of Operation

When automatic grounding and air-break switches are used at transformer stations, the circuit breakers at distant stations are given the double duty of protecting both the transmission line and the distant transformer. An automatic single-phase grounding switch, located on the 110-kv switching structure of a transformer station, is used to apply a solid line-to-ground fault on a transmission line whenever the protective relays of a transformer have detected a fault. The artificial line-to-ground fault is detected by ground relays at distant stations, causing circuit breakers to operate and disconnect the sources of energy from the faulted line. After the line is de-energized, an automatic 3-pole air-break switch is opened on the 110-kv side of the defective transformer to disconnect from the line both the transformer bank and the single-pole grounding switch. This combination of automatic switches allows a small transformer station to be supplied from a high-voltage transmission line without using an expensive 110-kv circuit breaker.

Since the trip circuit of the air-break switch is controlled by a pallet switch on the automatic grounding switch, a timer is usually put into the circuit to delay the tripping of the 3-pole automatic air-break switch by a time interval ranging from 0.5 to 3.0 seconds. During this interval, the distant circuit breakers will have time to interrupt the flow of fault current, and the automatic air-break switch can be opened with safety. With the faulted transformer removed from the system, automatic reclosing relays can close the circuit breakers after a time delay and restore the line to service.

General System Conditions Permitting the Use of Automatic Switches

Automatic grounding switches are not recommended for stations which supply part of a load along with local generation, because the artificial fault will cause a disturbance to both the system and local generation. For the same reason, they should not be used with transformers which are a tie between two parts of a large system where power might be transferred in either direction. This objection is reduced if the low-voltage circuit breakers are made to operate first, and the artificial ground fault is applied after a time delay. However, the distant circuit breakers are tripped after a longer delay, thereby giving slower clearance of the faulted transformer. In Table I, there are at least five installations which are exceptions to the above preferred system conditions. When the local station is connected to a source of generation on the low-voltage side, the 110-kv windings of the transformer should be star-connected with the neutral solidly grounded, to prevent damaging the insulation on the high-voltage winding.

Paper 49-143, recommended by the AIEE Substations Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer General Meeting, Swampscott, Mass., June 20–24, 1949. Manuscript submitted March 22, 1949; made available for printing May 4, 1949.

E. A. RICKER is an Assistant Relay Engineer with The Hydro-Electric Power Commission of Ontario, Toronto, Ontario, Canada.

Another factor which must be considered before deciding whether the high-voltage circuit breaker can be eliminated by the substitution of automatic switches, is the class of service that is required by the customers supplied from the station. Whenever any grounding switch operates at a station, the power supply for all customers is interrupted. If a station has two or more transformer banks with as many high-voltage circuit breakers, customers are not affected by faults in one transformer. If there is only one transformer bank at the station, service is not improved by using a circuit breaker in place of automatic switches. If the station has two banks of transformers, both equipped with automatic switches, and if the distant circuit breakers have automatic reclosing equipment, the local station has only a short interruption for a fault in one transformer, because the supply of energy to the load is restored as soon as the distant circuit breaker has been reclosed automatically.

Mounting of Automatic Switches

The single-pole automatic grounding switch usually is mounted near the automatic air-break switch. The steel structure might be used to support both. The grounding switch often is used to produce a circuit to ground across the insulator stack at the hinge end of the air-break switch, an extra contact jaw for the grounding switch being attached to the top casting on the stack of insulators.

The spring operated mechanism for the single-pole grounding switch usually is mounted near the hinge of the grounding switch; linkages extend the manual control to the ground level. Energy is stored in the springs by moving a lever through an angle which ranges from 90 to 180 degrees.

The box containing the spring-operated mechanism for the automatic 3-pole air-break switch usually is mounted nearer the base of the steel structure. The box is heavier and contains stronger springs which must be capable of breaking three contacts rated at 600 amperes each, and of moving the linkages and arms of three switches to the open position. Springs of different strength are combined to give extra force at the beginning of the travel and to overcome excess friction caused by corrosion of the contacts or obstructions such as ice formation. Energy is stored in the springs by operating a lever manually. The second movement of the lever returns the arms of the air-break switch to the closed position. Motor-operated mechanisms are available for winding up the springs. When the mechanism has been latched in the loaded condition, the lever can be used for opening or closing the switch manually to energize or isolate

a transformer while it is off load. Arcing horns are added to the switch to prevent burning the main contacts.

Both kinds of automatic switches have solenoids which are energized from the station battery for moving the trip-latch or moving a linkage through a neutral position. Both types of mechanism boxes contain pallet switches for opening circuits to trip coils and controlling other circuits to relays and lamps.

Since automatic switches are used at stations during the earlier stages of their growth, the supporting structure should be designed for the addition of a circuit breaker with the least modification. A 3-pole automatic air-break switch and a 3-pole disconnecting switch might be mounted on a steel structure above the place where the circuit breaker could be installed. The function of the extra disconnecting switch will be discussed later

Figure 4. Diagram of control circuits for automatic switches

with the procedure for tests. The foundations for the steel structure should be well made, so that wind and frost will not force the structure out of line and cause excessive friction in the bearings of the switches. Wood poles are not recommended as supports since they are more likely to be heaved by the frost, causing misalignment.

Arrangement of Equipment on Diagrams of Stations

In the simplest station having only one transformer, the low-voltage breaker might be omitted and fuses used. When the load includes synchronous motors or local generation, a circuit breaker is required to remove the source of fault current and to reduce interruptions to the high-voltage line by the operation of the overload protection on the transformer. When two or more banks are in parallel, low-voltage breakers are required to isolate the faulted bank. The breaker usually is tripped a short time before the artificial line-to-ground fault is applied to the high-voltage side of the faulted bank.

When two transformers are installed for reducing the duration of interruptions, the overload relays for each transformer should have settings which are greater than the combined loads of both banks, or else the second bank would be lost due to overload whenever the first bank develops an internal fault.

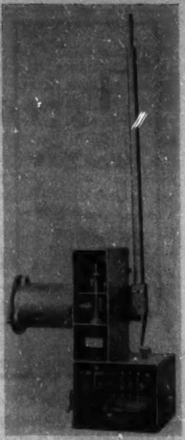

Figure 5. Automatic grounding switch with cover removed from mechanism box

Resistance of Station Ground

For successful operation of a scheme which includes automatic grounding switches, the protective equipment with the circuit breakers at the distant ends of the transmission line must include relays which are capable of detecting ground faults caused by automatic grounding switches. At some stations the resistance through ground might reduce the current to a value that cannot be detected by the relays at the distant station, as well as causing dangerous voltages in the local station. Considerable expense might be involved in installing numerous ground rods, in burying long bare-copper cables as counterpoise, or in extending a solid connection from the station to the nearest wet location. The alternatives are installation of high-voltage fuses or circuit breakers.

Testing Routine

Experience has shown that some installations of automatic switches are unreliable and require frequent testing. Since many of the troubles have developed in control circuits rather than in the switches themselves, the tests should be a complete check of the whole clearing process, from the closing of a contact at the panel to the final opening of the air-break switch. A push button usually is installed as a means of initiating the process. When

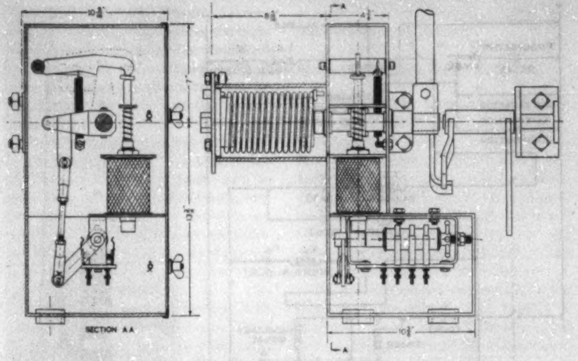

Figure 6. Assembly of mechanism for automatic grounding switch

low-voltage lines and switches are available for transferring the load of the small transformer station to another station, the test can be made during light load periods. When the station is in an isolated location, the tests are made during prearranged interruptions.

Tests on a station having a single transformer involve a complete interruption of the station. Load is removed from the transformer by tripping the low-voltage breaker. The exciting current of the transformer is broken by the air-break switch. A 3-pole disconnecting switch should be installed on the line side of the automatic air-break switch to permit the test being made without operating the breakers at the distant ends of the line. When the automatic switches have been isolated, the air-break switch should be reset to its normal operating position. Then the emergency push button on the control panel should be operated to trip the grounding switch and the air-break switch in their normal sequence. This test should be repeated once or twice to clean the contacts. The present practice is to make these tests monthly wherever possible. Whenever an automatic operation from one of the protective relays has occurred during a month, the routine monthly test can be omitted.

Gravity-Type Automatic Grounding Switch

The first installation of an automatic grounding switch was placed in service in 1930. A weight was added to one phase of an ordinary manually-operated line-grounding switch. The arm of the switch remained horizontal while in the normally open position. When the coil was energized, the latch was tripped, and the arm moved to the vertical position to ground the line. In its earliest form, the arm of the switch and the overbalancing counterweight were in a straight line. Experience showed that the angle of 180 degrees should be reduced by 30 or 45 degrees to produce a force which would keep the contact closed. Rebounding of the arm was reduced by using a resilient material in the jaw. Guides for the jaw and arcing horns were added.

There were only two installations of gravity-type switches, and no automatic air-break switch was used with them.

The mechanical design of the switch was the cause of failure to operate in four cases; troubles in control circuits prevented operation in six other cases. All failures except two occurred during routine tests.

Spring-Type Automatic Grounding Switch

This type of switch with its method of mounting already has been described. The stored energy is limited by the adjustments of the spring mechanism. Some looseness in the mechanism will allow a mechanical impact to break a coating of ice. Excessive spring pressures might cause damage at the jaw of the switch.

Troubles were recorded on 10 installations out of a total of 35, the auxiliary equipment being the cause of many of them. Nine cases of failure were caused by the mechanical parts not functioning properly; in 11 cases the operations of control circuits were incomplete or faulty. Only three of all these failures occurred during service; the others occurred during routine tests.

Spring-Type Automatic Air-Break Switches

At first, no automatic air-break switches were used. The list of troubles with these switches contains almost as many items as the list for the automatic grounding switches. For reliable operation the bearings should be noncorrodible, antifriction, and greaseless. Since the stored energy in the spring is large, there is greater pressure on the latch. The force from the tripping solenoid should be large enough to move the latch. The station should have at least a 48 volt battery and preferably a 125 volt battery. The higher voltage will avoid troubles caused by resistance in contacts and control wiring. The design should be chosen so that ice formation does not prevent operation to either the open or closed positions.

Among 32 installations, seven switches were the subject of 13 reports on troubles. Eight failures were caused by mechanical troubles and three, by control circuits. The cause of five other failures could not be determined. One failure occurred while the switch was in service; the others occurred during routine tests.

Motor-Operated Air-Break Switches

Due to slower operating speed of air-break switches with motor-operated mechanisms, the timer controlling the trip coil is often omitted. The motor usually is rated at one-quarter horsepower, and the full capacity of the station

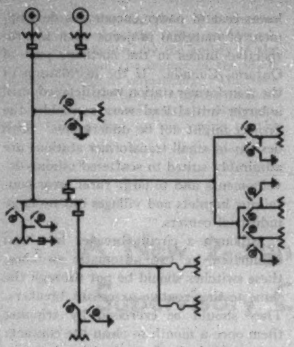

Figure 8. Growth by extension of branch circuits

battery is the stored energy available to operate it. In a total of over 16 installations, three of them were the subject of trouble reports.

One long interruption in service was caused by failure of lamps to indicate that a switch at a distant station had remained in the closed position. Other failures were found during routine tests. In one case the bevel gears had been broken by a person moving the lever for hand operation in the wrong direction. Another motor-driven switch had been operated by the controller to the open position, but it failed to close when the controller was turned to the close position. This failure might have been caused by ice or snow, as the temperature was −50 degrees Fahrenheit.

Experience with 39 Installations of Spring-Operated Grounding Switches

In Table I, 33 stations are listed in which automatic switches are used. The combined experience on the automatic grounding switches since the first one was installed in 1930, is a total of 260 switch years. The combined capacities of the transformers in these stations is 643,500 kva. In five of these stations with a total transformer capacity of 150,000 kva, circuit breakers were installed replacing the automatic grounding switches when fewer interruptions were required or when interconnections in the 110-kv network were changed. Construction is now proceeding on nine other stations with a total transformer capacity of 96,000 kva, including 11 automatic grounding switches and 13 air-break switches.

The range of transformer capacities, which are protected by a single grounding switch, extends from a minimum of 3,750 kva to a maximum of 67,500 kva. The three common bank capacities are 4,500, 8,000, and 15,000 kva. One station contains three banks with separate 110-kv air-break switches for each bank.

Transformer banks which have a rating of less than 3,000 kva usually are not equipped with bushing-type current transformers; therefore, protective relays cannot be used. High-voltage fuses serve as protective links and disconnecting devices for such small transformers.

Table I shows that most of the early stations were equipped with 24-volt storage batteries. Some of these have been replaced by others of higher voltage and ampere-hour capacity. The newer stations have batteries rated at 125 volts and at least 160 ampere-hours. In the northern districts, where low temperatures are common in the winter, smaller batteries were installed. These required less heated space in the station, but they were a sacrifice of reliability. The number of low-voltage circuit breakers in a station, the frequency of tripping and closing them, and the amount of other motor-operated station equipment will be factors in deciding the size of the station battery.

Typical Installations of Automatic Switches in Stations

Small transformers stations can be supplied from a radial line, or a single tie line, or from either of two tie lines supported on double-circuit towers. These connections are illustrated in Figure 1. When a single-circuit line is intended for use as either a tie line or a radial feeder, additional manually-operated disconnecting switches are installed, as illustrated in Figure 1(C). Figure 1(D) shows how a small station can be connected to either of two parallel tie lines. Except when the tapped station is being transferred from one circuit to the other, the high-voltage lines are never connected in parallel.

None of these diagrams shows any method for testing the automatic switches. Figure 2 shows how manually-operated switches can be added to the stations in Figure 1, so that the automatic switches can be given a complete test without tripping circuit breakers on the 110-kv supply lines.

A station with two banks of transformers is shown in Figure 3(A). One manually-operated disconnecting switch can be added to this diagram, as shown in Figure 3(B), so that the automatic switches can be tested easily.

The equipment which is not essential for this discussion has been omitted from all of these diagrams, such as disconnecting switches associated with high-voltage circuit breakers, line sectionalizing switches and transfer switches, coordinating gaps, lightning arresters, and line grounding switches that are closed before maintenance work is done on the 110-kv lines. A typical diagram of control circuits for automatic switches is shown in Figure 4. Figure 5 shows the mechanism and blade of the grounding switch in the tripped position. The assembly of the tripping mechanism is shown in Figure 6.

Typical System Connections

The relation of the small transformer stations and the tapped lines to the other parts of the system is shown in Figures 7 and 8. The latter shows growth by the extension of branch circuits with the addition of two circuit breakers in the

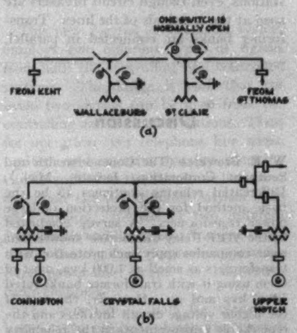

Figure 9. Tapped stations on loop lines in a 110-kv system

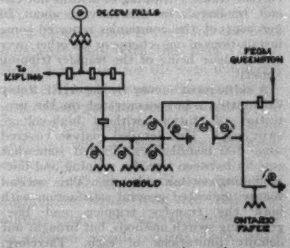

Figure 10. Motor-operated switches in tie lines

main branches. The main disadvantage is that faults which occur on the main supply line cause an interruption to stations on the branch lines as well. A total of seven stations is illustrated in Figure 8.

Figures 9 and 10 show loop lines which supply tapped stations. The loop in Figure 9(A) is closed only during an emergency or to transfer load, because the terminal stations are connected by other transmission lines. In Figure 9(B) no other lines connect these stations; all disconnecting switches remain in the closed position for normal operation. Under these conditions, the loop lines are actually single-circuit tie lines. Figure 10 shows two stations which are operated with tie lines closed through automatic motor-operated disconnecting switches.

Economy by Use of Automatic Disconnecting Switches

The infrequent occurrence of faults in transformers has resulted in the elimination of high-voltage circuit breakers for transformers from nearly all transformer stations, even though circuit breakers are used at the terminals of the lines. Transformer banks are connected in parallel, and automatic motor-operated disconnecting switches on the high-voltage side and low-voltage circuit breakers are used to isolate the faulted bank after the auxiliary tripping relay has operated to disconnect all sources of fault current.

Low-voltage windings on transformers usually are delta-connected, and zig-zag grounding reactors are used as sources of ground current to the feeders. Since faults in grounding reactors do not occur frequently, 3-phase circuit breakers between the terminals of the reactor and the station bus usually are omitted. An automatic motor-operated disconnecting switch is used in place of the circuit breaker to disconnect the zig-zag grounding reactor after all sources of fault current flowing into the low-voltage bus have been removed by operation of the circuit breakers.

Conclusions

Omitting high-voltage circuit breakers from a station gives a considerable saving in capital, but it is accompanied by more interruptions of the power supply to the customers. The reduced carrying charges permit lower rates for electric energy being charged to the customer. The lower cost of power encourages development of marginal projects, such as prospective mines in the northern part of Ontario, Canada. If the installation of the transformer station were delayed until a larger initial load were available, the project might not be undertaken. Such designs of small transformer stations are admirably suited to scattered mining developments and to large rural areas containing hamlets and villages but no large industrial centers.

Although a circuit breaker has been eliminated by two automatic switches, these switches should be put through the same testing routine as circuit breakers. They should be exercised by tripping them once a month to clean the contacts and to check the control wiring for open or short circuits. The stored-energy source for operating the automatic switches should be effective through the whole travel of the switch with a safe margin.

Energy stored in springs appears to be sufficient for single-pole grounding switches. The larger amount of stored energy in the station batteries and motor-operated mechanisms would be preferred for opening the 3-pole air-break switches.

Discussion

W. R. Brownlee (The Commonwealth and Southern Corporation, Jackson, Mich.): Differential relaying continues to be the basic method for the protection of large power transformers. A survey conducted by the AIEE Relay Committee[1] showed that some companies apply such protection with transformers as small as 1,000 kva, most of them using it with transformer banks rated 5,000 kva and up. However, the cost of the higher voltage circuit breakers and the remarkable improvements in the reliability of modern power transformers have led to the substantial application of local differential relaying, either with automatic line grounding switches or with pilot wire or carrier current transfer tripping of distant line circuit breakers. In this survey, about 75 per cent of the companies reported some installations of one scheme or the other, over half of these being of the transfer tripping variety.

A subsequent survey by the AIEE Relay Committee was concentrated on the protection of stations without high-voltage switching.[2] This detailed analysis covered some 100 installations, divided somewhat equally between transfer tripping and line-grounding switch schemes. This second survey indicated general satisfaction with both the transfer tripping and line-grounding switch methods, but brought out definite limitations of each. Therefore, this detailed analysis of application and performance presented by the author is most timely and should assist in a more accurate evaluation of the proper field for automatic grounding switches. It would be interesting to learn what consideration the author gave to the use of transfer tripping schemes, and the reasons for preferring the automatic grounding switch method.

Speed of operation of the automatic grounding switch is rather important, since its operating time plus that of the ground relays at remote stations adds directly to the total time of fault clearing, when comparing this scheme with either a local circuit breaker or transfer tripping arrangement. The time of operation of the type of spring-operated grounding switches described by the author would be of interest (from energizing the trip coil until the contacts touch).

In view of the relative infrequency of faults in modern power transformers, it seems unfortunate that the grounding switch scheme requires interrupting the load for test purposes, in the case of single transformer installations, as often as once a month. Consideration might be given to additional disconnecting and by-pass facilities to avoid interruptions during tests, but it is doubtful if this added complication and expense would be justified.

Increased speed of operation of automatic grounding switches and improved reliability of the entire scheme seems highly desirable. Accordingly, designs based on a straight line motion might be preferable for line grounding switches.

E. A. Ricker: The discussion of the automatic grounding switch would not have been complete without references to surveys by the AIEE Relay Committee and reports which were published in AIEE Transactions for 1948 and 1949. For this favor, grateful acknowledgment is given to W. R. Brownlee.

Although the second general survey by the Relay Committee showed that both the transfer tripping and line grounding switch methods of opening circuit breakers in remote locations will perform correctly in the majority of operations, automatic grounding switches have been preferred by the Hydro-Electric Power Commission for several reasons. Carrier equipment for transferring tripping signals has been shown by tests to be not always effective and reliable. Carrier transmitters and receivers require more maintenance and adjustment by specially-trained personnel. The cost of a complete installation of carrier equipment is higher than the cost of installing additional supports and switches associated with the automatic grounding device. No power is required by the automatic switch during the standby condition.

The time delay in operation of the grounding switch was made small by using light materials in the blade to reduce its inertia and co-ordinating designs for the spring, trip latch, and jaw. The amount of energy stored in the spring can be adjusted. It is limited by the ability of the jaw to withstand the impact of the blade without damage or rebounding. The force caused by current in the tripping solenoid must be several times greater than the opposite force caused by the spring on the trip latch even after months without an operation. Automatic grounding switches are normally adjusted so that the time delay is less than 0.5 second from the time the trip coil is energized until the blade makes contact with the jaw of the switch.

To all employees of the Hydro-Electric Power Commission of Ontario who gave assistance by providing opportunities to review records of operating conditions, who passed on their knowledge of early developments, who gave suggestions on the contents of this paper, and to those who prepared the drawings, the first copies of the text and checked the material, the author acknowledges a debt of gratitude.

A New 2-Signal Synchronous Supervisory Control System

W. A. DERR
MEMBER AIEE

THERE are two fundamental methods of selecting a desired unit in a supervisory control system. The one method, known as direct selection, is based on applying signals which are different for each unit. The other method, known as synchronous selection, is based on having both the controlling and controlled station equipment connect to each unit in sequence until the desired unit is reached.

Two different types of direct selection systems have been manufactured. One of these types uses a different code of pulses to select each desired unit, with the station receiving the selection pulses returning a similar code of pulses to verify the correctness of selection.[1] The other type also employs a different code of pulses to select each desired unit, but the coding is made so that only the correct unit can be selected. With this latter type it is necessary only to verify that a selection has been made and not that a particular selection has been made.[2]

In a synchronous system there is no specific code or signal associated with each individual unit which must be selected. Instead, signals are transmitted which cause the controlling and controlled station equipment to step through each unit in sequence and in synchronism. The equipment stops when the desired unit is reached. A new system based on synchronous selection will be described in this paper.

All supervisory control systems require signal responsive elements at the controlling station and at the controlled station. Direct selection systems are available which require only a single type of signal and hence a single signal responsive element at each location.[1,2] However, a minimum of two different types of signals must be employed to provide a reliable synchronous system.

When different signal responsive elements are employed at the controlling station and at the controlled station for each station controlled, it is known as single station operation. This is the basic arrangement for which either direct selection or synchronous selection systems are applicable.

The control of several stations employing common signaling means at the controlled stations as well as at the controlling station is known as multistation operation. Direct selection systems using a single signal responsive element at each location are the only systems which are practical to use for multistation operation. Multistation operation is advantageous when only a single pair of wires or a single power-line carrier channel is available for the control of several stations since only one type of signal must be provided.

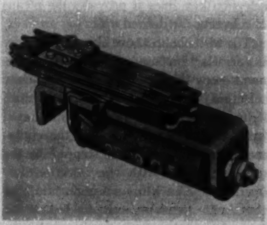

Figure 1. Type of relay employed in new system

Since a reliable synchronous system must employ a minimum of two different signals, multistation operation is not practical.

The synchronous principle provides for rapid checking of the position of devices supervised. A synchronous system also is advantageous where functions must be performed consecutively, since it is only necessary to step to each unit in turn, thus reducing the operating time.

Principle of Operation

This new 2-signal synchronous system employs two different types of signals from both the controlling and controlled stations. The design is such that the same two signals can be used from the controlling and controlled stations. Thus, for operation over telephone line wires, positive and negative battery potential can be applied to the telephone line wires to obtain the two different signals from each station. Signals of two different frequencies can be used from each station as the signaling means for operation over power-line carrier or microwave radio channels.

The selection of units for control is based on the principle of stepping through each unit in turn until the desired unit is reached. A single pulse is used for each step, with all stepping pulses originating from the controlling station. One of the two types of signals employed at the controlling station is used for the odd-numbered steps with the other type of signal being used for the even-numbered steps. Thus the same signal never repeats itself for consecutive steps. This prevents the possibility of the controlling and controlled stations ever operating out of step.

The controlling station waits for a supervision signal from the controlled station after each stepping pulse. The supervision signal consists of a single pulse of either of the two types of signals used at the controlled station. Thus, the

supervision pulse verifies or changes the lamp indication for the particular unit and also provides the signal that the stepping can continue.

A better picture of the stepping arrangement just described can perhaps be obtained by referring to Table I. This table indicates the signal pulses which would be employed for a supervisory control system providing control and supervision of ten units (for example, circuit breakers), with the first five units being in one position (open) and the last five units being in the other position (closed).

When the stepping is started by the operation of a selection key, the stepping stops when the unit associated with that particular key is reached. Such selection of a desired unit is referred to usually as point selection. When a unit or point has been thus selected, it is possible to initiate the control signals. Signal number 2 is used for both control functions which can be performed, with the number of pulses of this signal determining the control function. For example, two short pulses constitute the control code for closing a circuit breaker and three short pulses constitute the control code for tripping a circuit breaker.

A long pulse of signal number 1 is transmitted from the controlling station to prepare for stepping from the normal at rest condition or for stepping after a unit has been selected. The use of a long pulse eliminates the possibility of unwanted stepping from any extraneous disturbing voltages to which the signal receiver elements may be subjected.

A long pulse of signal number 2 is transmitted from the controlled station if any supervised device changes position automatically. Receipt of this signal at the controlling station results in a long pulse of signal number 1 being transmitted from the controlling station to initiate stepping. When stepping is thus initiated due to an automatic operation at the controlled station, and position of all devices supervised is checked in sequence.

Following is a list of the different signaling means employed in the operation of this system, as just described:

From Controlling Station	
Start	Long pulse, signal number 1
Odd steps	Short pulse, signal number 1
Even steps	Short pulse, signal number 2
Close control	Two short pulses, signal number 2
Trip control	Three short pulses, signal number 2
From Controlled Station	
Alarm	Long pulse, signal number 2
Close supervision	Short pulse, signal number 1
Trip supervision	Short pulse, signal number 2

Operating Features

The supervisory control system described in this paper is an all-relay system employing telephone-type relays as shown in Figure 1.

An escutcheon or key and lamp plate as shown in Figure 2 is used at the controlling location for any of the following functions which may be performed:

1. Control and supervision of any device. (For example, a circuit breaker.)
2. Supervision and alarm of any device. (For example, indication of high transformer temperature.)
3. Telemetering of any quantity. (For example, telemetering of kilowatt load.)
4. Control of any device with simultaneous telemetering of quantity controlled. (For example, control of tap changer with simultaneous telemetering of tap changer position.)

The key at the bottom of the escutcheon shown in Figure 2 is a pull-type key which is operated to initiate stepping of the equipment. This key is called a selection key since it provides the means of selecting the desired unit.

The white lamp above the selection key is the selection lamp. When the equipment steps through each unit, the white selection lamps associated with each unit, light in turn. If the stepping is initiated by operating a selection key the equipment stops when it has stepped to the unit associated with the selection key operated. The white selection lamp for that unit then remains lighted. The desired operation on that unit can then be performed after which the pull-type selection key should be restored. When the key is thus restored, the equipment proceeds to step through the rest of the units.

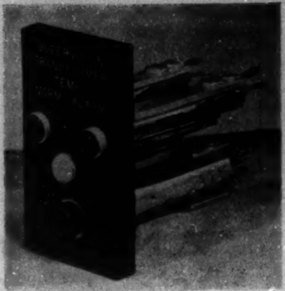

Figure 2. Escutcheon used in new system for each unit controlled and supervised

The two upper lamps on the escutcheon shown in Figure 2 are for indicating the position of the device supervised. If the device supervised is a circuit breaker, these would of course be red and green lamps to indicate whether the circuit breaker was closed or open. If the escutcheon is used for a telemetered indication or for control and simultaneous telemetering, these position indicating lamps are omitted.

To indicate the automatic change of position of a device, the associated position indicating lamp on the escutcheon is flashed. For example, if a circuit breaker is tripped by a protective relay, the green lamp on the escutcheon for that circuit breaker is flashed in addition to an alarm bell being sounded. If a circuit breaker which is equipped with an automatic recloser, trips and is reclosed successfully, the green lamp on the associated escutcheon at the controlling station is first momentarily flashed, after which the red lamp is flashed.

There are five common push-type keys used at the controlling station in the operation of this system. Two of these keys are the control keys which are operated after a unit is selected to change the position of the device controlled. For example, considering a circuit breaker, one of these keys would be operated after selection to close the circuit breaker. The other key would be operated after selection to trip the circuit breaker.

The third common key is designated as the reset key. Operation of this key causes the system to step through all of the points. Thus, it performs the function of checking the position of all of the devices supervised since the position indicating lamps are checked on every step. Operation of this key also restores the equipment to normal in the event that it is off normal for any reason.

The fourth common key is operated to silence the audible alarm which is initiated when any supervised device changes position other than by operation of the supervisory control equipment.

The fifth common key is operated to cause any position indicating lamp or lamps which may be flashing as a result of automatic change of position of the devices supervised to be lighted continuously.

The system is suitable for use with any of the commonly employed types of telemetering equipment. Voltage or current magnitude types as well as impulse types can be used when operation is over telephone line wires. For operation over power-line carrier or microwave radio channels, impulse-type telemetering equipment must be used. It is possible to have the telemetering circuits arranged so that any telemetered indication can be continuously received while the equipment is at rest, without interfering with any other operations. This can be done regardless of the channel means employed.

Communication can be provided readily over the same pair of wires used for operation of the supervisory control equipment. It is customary to have the telephone ringing function provided by the supervisory control equipment.

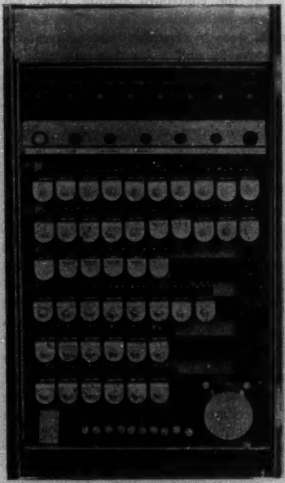

Figure 3 (A). Controlling station end of 2-signal model

When several units are to be controlled or several telemetered readings taken, it is not necessary to step through all of the units for each selection to be made. The selection keys of all of the desired units may be operated one after another. When this is done the equipment will step as far as the unit associated with the first selection key. Then, when this key is restored the equipment will only step to the next unit for which the selection key had been operated. This arrangement is particularly advantageous when there are a number of telemetered readings which must be checked at frequent intervals, since a large number of readings can be obtained very rapidly.

Whenever any supervised device changes position automatically at the controlled station, all points are stepped through with the lamp indications being changed for the unit or units which changed position. If any supervised unit changes position after it has been stepped past, the equipment immediately steps through all of the points a second time as soon as the first cycle of stepping has been completed. Thus, no changes of indication will be missed.

Approximately ten points are stepped through in a second. Thus, if fifty circuit breakers are controlled and supervised, the position of all of the circuit breakers can be checked in five seconds.

Figure 3 shows the controlling and controlled station equipment of a model of this new supervisory control system which is being used in microwave operation on the property of the Pennsylvania Electric Company. This model is designed for the control and supervision of six circuit breakers and two selective telemetered indications.

Detailed Description of Operation

To describe the operation of this new system, partial schematic diagrams only showing the particular elements involved in the operation being described are presented. Only those circuits necessary to obtain an understanding of the circuit arrangements which can be used to provide for operation on the principle of operation described previously are presented.

On the diagrams to be described, only those coil circuits are shown which were deemed necessary. In some cases only the contacts of relays are shown. For such cases, the time at which the coils of these relays would be energized and de-energized is described.

Following is a description of the elements shown on the partial schematic diagrams of Figures 4 to 10 inclusive:

	Contact of relay which closes when relay is energized or operated.
	Contact of relay which is closed when relay is de-energized or released.
	Fast type telephone relay.
	Telephone relay with copper sleeve around core to delay release when it is de-energized.
	Polarized telephone type relay.
	One coil of two coil telephone relay. Relay will operate when either coil is energized.
	Resistor.

CHANNEL ELEMENTS

Figure 4 indicates how signals are applied and received on the basis of positive and negative d-c pulses being used for signaling. It will be noted from this figure that a single polarized relay (LR) is connected to the line wires at both the controlling and controlled stations through break contacts of all of the relays which can apply potential to the line wires.

Figure 5 indicates how signals are ap-

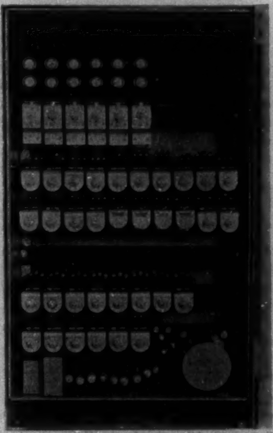

Figure 3 (B). Controlled station end of 2-signal model

plied and received on the basis of two different frequencies being used for signaling, instead of positive and negative d-c pulses with the same two frequencies being used from each station. This necessitates the use of break contacts of the signaling relays in the receiver relay circuits. If two different frequencies are used from each station these break contacts are not required.

With reference to both Figures 4 and 5, the relay contacts shown in the signaling circuit at the controlling station are operated to transmit signals as indicated below:

Relay 1—Transmits odd stepping pulses to controlled station and steps odd point relays at controlling station.

Relay 2—Transmits even stepping pulses to controlled station and steps even point relays at controlling station.

Relay 3—Transmits starting pulse.

Relay 4—Transmits operation control pulses. ("Trip" and "close" pulses in the case of circuit breakers.)

At the controlled station, relay 1 operates after each step to send the supervision pulse. Relay 1 also operates to transmit the alarm signal. Relay 2 determines which of the two supervision pulses is transmitted. In the description which follows, these will concern the indication of circuit breaker positions and will be referred to as "close" and "trip" supervision pulses. When relay 2 is energized a close supervision pulse is transmitted and when relay 2 is de-energized a trip supervision pulse is transmitted.

STEPPING CIRCUIT

Figure 6 shows the essentials for stepping at the controlling station. Figure 7 shows the essentials for stepping at the controlled station. The stepping pulses are all transmitted from the controlling station.

With reference to Figure 6, the relays shown which were not mentioned previously, perform the following functions at the controlling station:

Relay 5—Energized when stepping stops and a point is selected.

Relay 6—Energized to start stepping pulses and released at end of first step.

Relay 7—Operates from contact LR1 on receipt of "close" supervision.

Relay 8—Operates in series with odd-numbered point selection relays.

Relay 10—Operates in series with even-numbered point selection relay

Relays A1, A2, and so forth—Point selection relays.

With reference to Figure 7, the relays shown which were not mentioned, previously, perform the following functions at the controlled station:

Relay 3—Energized by starting pulse which precedes stepping pulses and remains energized until stepping pulses from controlling station stop.

Relay 4—Operates in series with odd-numbered point selection relays.

Relay 5—Operates in series with even-numbered point selection relays.

Relay 6—Operated by starting pulse which precedes stepping pulses. Releases at end of first stepping pulse.

Relays F1, F2, and so forth—Point selection relays.

Relays G1, G2, and so forth—Point indication relays. Each *G* relay is operated if the associated circuit breaker is closed.

Stepping is started from the controlling station as a result of operation of a point selection key, operation of the reset key or receipt of an alarm signal from the controlled station resulting from the automatic operation of a supervised device.

To start the stepping, relay 6 is energized at the controlling station. A contact of relay 6 completes a circuit for energizing relay 1. Contacts of relay 1 transmit the first stepping pulse to the controlled station as shown in Figures 4 and 5. Another contact of relay 1 energizes A1 and 9 in series at the controlling station. When relay 9 is thus energized it opens the energizing circuit of relay 1. When relay 1 releases it removes the first stepping pulse from the channel and opens the energizing circuit for relays A1 and 9. However, these two relays remain energized through a make contact of relay A1 and break contacts of relays 2 and 10 in parallel. The controlling station then waits for the first supervision pulse from the controlled station. It is to be noted that relay 6 releases at the controlling station after the first stepping pulse is transmitted.

When the first stepping pulse is received at the controlled station, relay LR is energized and contact LR1 closes. Relays F1 and 4 are energized then in series. When relay 4 is energized it completes a circuit to energize relay 2 providing relay G1 is energized as a result of the associated circuit breaker being closed. Assume that relay 2 is energized as a result of relay G1 being energized.

When the first stepping pulse is removed from the channel, contact LR1 opens at the controlled station, which results in relay 1 being energized in series with relays F1 and 4. When relay 1 is energized the supervision pulse is transmitted to the controlling station. Which of the two supervision signals is transmitted is dependent on whether or not relay 2 is energized at the time. The energizing of relay 1 releases relay 6, which allows relay F1 to remain energized but releases relays 1 and 4. The supervision pulse is removed from the channel when relay 1 releases.

Receipt of the close supervision pulse at the controlling station results in relay LR being energized, contact LR1 in turn energizing relay 7. The energizing of relay 7 results in the lamp indication on point number 1 being changed to red if it was not already red. The red and green position indicating lamp circuits will be discussed later.

When the supervision pulse is removed from the channel, relay 2 is energized in series with relay 7. Contacts of relay 2 transmit the second stepping pulse to the controlled station. Another contact of relay 2 energizes relays A2 and 10 in series. At the controlling station, when relay 10 is thus energized it de-energizes relays A1 and 9 and also opens the energizing circuit of relay 2. When relay 2 releases it removes the second stepping pulse from the channel and opens the energizing circuit for relays A2 and 10. However, these two relays remain energized through a make contact of relay A2 and break contacts of relays 1 and 9 in parallel. The controlling station then waits for the second supervision pulse from the controlled station.

At the controlled station, relay LR is energized and contact LR2 closes when the second stepping pulse is received. Relays F2 and 5 are then energized in series. When relay 5 is energized it completes a circuit to energize relay 2 providing relay G2 is energized as a result of the associated circuit breaker being closed. Assume that relay G2 is not energized, thus leaving relay 2 de-energized.

When the second stepping pulse is removed from the channel, contact LR2 opens at the controlled station, which results in relay 1 being energized in series with relays F2 and 5. When relay 1 is energized, the second supervision pulse is transmitted to the controlling station. The energizing of relay 1 also releases relay F1. When relay F1 releases, relays 1 and 5 are de-energized but relay F2 remains energized.

Receipt of the trip supervision pulse at the controlling station results in relay LR being energized, contact LR2 then energizing relay 8. The energizing of relay 8 results in the lamp indication on point number 2 being changed to green if it was not already green.

Figure 7. Fundamental circuits for controlled station stepping and supervision

When the supervision pulse is removed from the channel, relay 1 is energized in series with relay 8. Contacts of relay 1 transmit the third stepping pulse to the controlled station.

In a similar manner, stepping is continued through all of the points. If the stepping is started by the operation of a selection key, relay 5 is energized when the A relay associated with the selection key operated is energized. Thus, the stepping stops with the proper A relay energized at the controlling station and the proper F relay energized at the controlled station.

If the stepping is started from an alarm signal or the reset key, the stepping continues through all of the points.

Control Sending and Receiving

Figure 8 shows the essentials for transmitting the control pulses. After a unit has been selected by operation of a selection key, the desired control code is initiated at the controlling station by operation of the close key or the trip key. The close code consists of two pulses and and trip code consists of three pulses. Figure 9 shows the essentials for receiving the control pulses at the controlled station.

With reference to Figure 8, the relays indicated which were not mentioned previously, perform the following functions at the controlling station:

Relays 11, 12 and 13—Control counting chain relays. Count trip and close pulses.

Relay 14—Operates in conjunction with relay 4 to transmit control pulses.

With reference to Figure 9, the relays which were not mentioned previously perform the following functions at the controlled station:

Relay 7—Operates from contact LR2 on receipt of control pulses. Energizing circuit not completed until after point selection.

Relay 8—Slow-to-release relay associated with control counting chain. Remains energized during receipt of trip or close pulses and releases when pulsing stops.

Relay 9—Slow-to-release relay which maintains control circuit closed long enough to allow circuit breaker to operate.

Relays 11, 12, and 13—Control counting chain relays. Count trip and close pulses.

Relays C1, C2, and so forth—Close interposing relays which complete circuits to circuit breaker closing relays.

Relays T1, T2, and so forth—Trip interposing relays which complete circuits to circuit breaker trip coils.

If the trip key is operated at the controlling station after a point is selected, relay 11 is energized. Relay 4 is then energized through a make contact of relay 11 and relay 4 in turn energizes relay 14. A break contact of relay 14 then opens the coil circuit of relay 4. Relays 4 and 14 then continue to operate each other as long as any of the relays 11, 12, or 13 are energized.

With reference to Figure 4, it will be noted that a pulse is transmitted to the controlled station each time relay 4 is energized at the controlling station.

On the first operation of relay 4 after the trip key is operated, relay 12 is energized in series with relay 11. When relay 4 releases, relay 11 releases but relay 12 is held energized through its other coil. The next operation of relay 4 energizes relay 13 in series with relay 12. When relay 4 again releases, relay 12 releases but relay 13 is held energized through its other coil. The third operation of relay 4 de-energizes relay 13. Then when relay 4 releases, relay 14 is also de-energized and the circuit returns to its normal position.

The operation is similar when the close key is operated except that relay 12 is energized rather than relay 11. This results in a code of only two pulses being transmitted.

At the controlled station, receipt of the control pulses results in relay 7 being energized and de-energized from contact LR2. With reference to Figure 9, the first operation of relay 7 energizes relay 8. A contact of relay 8 in turn energizes relay 9. When relay 7 releases, relay 11 is energized. Relay 8 is a slow-to-release relay which will not release until the control pulses have stopped.

The second operation of relay 7 energizes relay 12 in series with relay 11. The second release of relay 7 de-energizes relay 11 but relay 12 is held energized through its other coil. Similarly, on the third control pulse relay 13 is energized in series with relay 12 and relay 12 is de-energized when relay 7 again releases.

When the pulsing stops relay 8 releases, completing a circuit to the T or the C relay of the point previously selected depending on whether relay 12 or 13 is energized. Relay 12 or 13 releases when slow-to-release relay 9 releases.

The supervision pulse is then transmitted to the controlling station in a manner similar to that described previously. The circuits for transmitting the supervision pulse at the end of a control operation are not shown.

Change of Indication

Figure 10 indicates how the change of indication of the red and green circuit breaker indicating lamps is accomplished at the controlling station when supervision pulses are received from the controlled station. Relays B1, B2, and so forth are the lamp indication relays, the red lamps being lighted through make contacts of these relays and the green lamps being lighted through break contacts of these relays.

As described previously, relay 7 is energized when a close supervision pulse is received and relay 8 is energized when a trip supervision pulse is received. The B relays are connected to make contacts of relays 7 and 8 through contacts of the associated A point selection relays as shown in Figure 10. The contact of relay 7 completes a circuit to energize the particular B relay. When a B relay is thus energized it seals itself in through a resistor. The contact of relay 8 shunts the particular B relay and causes it to release.

Conclusions

The 2-signal synchronous supervisory control system described is well adapted for the control of any size single station on telephone line wires and also is well adapted for operation on microwave radio channels.

The use of positive and negative d-c signals on either cable or open construction telephone line wires is preferred over the use of signals of two different frequencies for the following reasons.

1. Frequency signaling results in greater susceptibility to interference from electrical disturbances as well as from other services in adjacent or nearby telephone line wires.

2. Frequency signaling is more likely to interfere with services in adjacent or nearby telephone line wires

3. Frequency signaling necessitates the use of expendable parts such as tubes.

4. For operation over long distances of cable wires, repeaters may be necessary with frequency signaling. D-c signaling has been employed over cable wire lengths in excess of 100 miles.

It is to be noted that open construction telephone line wires can be adequately protected for d-c signaling.[3]

The fact that positive and negative pulses can be employed in the system

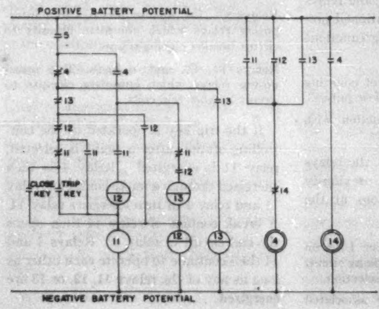

Figure 8 (left). Fundamental circuits for transmitting control pulses from controlling station

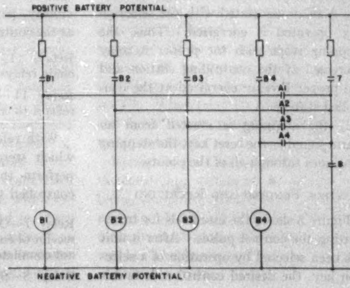

Figure 10 (right). Position indicating relay circuits at controlled station described means that the preferred d-c signaling means can be used on telephone line wires. If the system is used to control more than one station on a single pair of wires, frequency signaling must be employed for all except one station. For this case, different frequency pulses must be employed for each station controlled.

For power-line carrier operation, a direct selection system using a single type of signal is to be preferred when it is feasible to key the carrier frequency itself as the signaling means.[4] However, there are some cases in which supervisory control must share a single carrier channel with such services as continuous telemetering and automatic load control. This makes it necessary to operate the supervisory control equipment on modulating audio frequencies regardless of the signal requirements of the supervisory control equipment. For such applications the synchronous system described can be applied by using two modulating audiofrequencies to provide the two necessary signals.

The synchronous system can be applied to microwave channels by using two subcarrier or audio modulating frequencies for signaling. This system is well suited for microwave operation, since with the interference problem being essentially eliminated at these frequencies, the use of two modulating frequencies instead of one is no disadvantage.

The system described is fast in operation, a complete check of the position of 50 supervised devices being accomplished in approximately five seconds.

The synchronous system provides for extremely rapid consecutive selection of units. This is a desirable feature when a number of selective telemetered indications must be checked at frequent intervals.

The system of signaling and the check and guard features incorporated in the design assure correct selections and indications.

For applications where either a direct selection system or the synchronous system described could be used, the choice should be governed by the particular requirements of that application.

Discussion

P. W. Schirmer and **J. J. Winsness** (General Electric Company, Philadelphia, Pa.): The supervisory system described in this paper has some design and circuit simplifications. However, its application seems somewhat limited. It does not appear to be suitable for multistation application. Also, if used with carrier the additional cost of equipment for two audio tones is necessary. It has been our experience that there have been objections to the use of locking pull key for selection, because if the operator neglects to reset the key after completing an operation, the equipment remains tied up to the selected point and cannot transmit changes of indication from the remote to the control station.

In addition to these comments, there are certain questions, the answers to which are not clearly brought out in the paper. These are as follows:

1. What would be involved in expanding an equipment with a given number of points to one with a greater number of points after installation?
2. What is the maximum number of points available in a standard equipment and in what steps or groupings can these points be furnished?
3. What happens if one station gets an impulse from an outside interference when the other station does not?
4. Are unit assemblies of relays easily removable?
5. Can telemetering be put on the same point with control and indication?

W. A. Derr: The following comments apply to the discussion submitted by Mr. Schirmer and Mr. Winsness.

The types of applications for which this new system is most suitable are outlined in the conclusion of the paper. As stated in the seventh paragraph of the paper, the new system is not suitable for multistation applications.

Both locking-type pull keys and spring-return push keys have been used on supervisory control systems. Which type is preferable is a matter of personal opinion. The system as described in the paper is based on the use of pull-type keys. However, push-type keys could be used with a small additional amount of equipment.

The following answers apply to the numbered questions of the discussion submitted by Mr. Schirmer and Mr. Winsness.

1. Since no individual selection codes are involved in a synchronous system, it is simpler to increase the capacity of such a system than for any direct selection system. It is only necessary that space be available for mounting the necessary additional escutcheons and relays.
2. There is no limitation on the maximum number of points which can be provided. The equipment can be provided for any desired number of points.
3. If any number of short pulses are received at only one station due to interference, the equipment will not respond since long pulses are involved in starting the equipment. If a long pulse of the proper signal is received due to interference, the equipment will master check. Interference will not result in selection of an individual point.
4. The method of relay assembly is a construction feature. The paper has presented the principles and operation details of a new system and has not discussed construction features. However, this new system is as readily adaptable to various types of assembly and relay groupings as any other all-relay system.
5. Telemetering can be provided on the same point with control and indication with the new synchronous system just as can be done with direct selection systems.

Power Line Carrier for Relaying and Joint Usage—Part I

G. W. HAMPE
MEMBER AIEE

B. WADE STORER
ASSOCIATE AIEE

THIS is offered as the first of a pair of papers which are intended to summarize a number of principles and ideas that are in line with standard practices in carrier and related fields, to emphasize points of uncertainty and controversy, and to explore a number of ideas, both new and old, that are not necessarily standard, but do not deviate widely from what is, or potentially could be, done with existing equipment.

The second part of this paper will deal with these potentialities, and will show that more efficient use may be made of modern power line carrier channels, resulting in substantial economies and in conservation of the carrier frequency spectrum.

Need for Evolution in Carrier Usage

As the title indicates, the point of view is that relaying is a primary carrier function, even though the emphasis on specialized forms of relaying, singly and in combination with other specific functions, is reserved for the second paper under the same title. There are several reasons why carrier relaying is useful in place of, or in addition to, other relay schemes. Until recently, the principal one has been that any system of speedy and reasonably adaptable relaying for *ground* faults has been a pilot scheme, whether by wire, power line carrier, or (quite recently) by space radio. If the recently-developed ground distance relays prove effective[1] they will probably be adapted to work with carrier, resulting in decreased complexity and greater reliability in the control of carrier for ground fault relaying on those systems where the neutrals are essentially solidly grounded. Not all systems are of this type, and even on such systems faults-to-ground range from severe to quite limited, hence other means, perhaps electronic,[2] for simplified carrier control also would be desirable. Statements that limited faults to ground do not need quick clearing are to be discounted for the following reasons:

1. An extended fault arc frequently involves another phase conductor, and occasionally another line.
2. If longitudinal motion of the arc is limited by ice, a static (ground) wire, or even a conductor, may be burned in two.
3. If a static wire has its steel core exposed by an arc, and the burn is not located and repaired, corrosion will cause eventual breakage, probably under ice loading. This danger, which is greater for some types of static wire than others, also may apply to line conductors to some extent.

The newer factors which make it necessary that carrier relaying continue to evolve are immediate automatic reclosing, and the multiterminal line.[3] Economic pressure is forcing power system designers to adopt these, sometimes both on the same line, and means of efficient relaying must be found. The writers predict that such relaying will involve pilot channels, many with carrier as a pilot medium, and that some of them will involve hybrid combinations of relaying principles such as are to be set forth in the second paper.

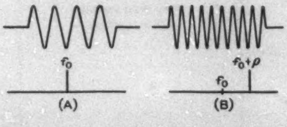

Figure 1. (A) Unmodulated carrier which might be keyed on and off. (B) A side frequency of a suppressed carrier, resulting from a single tone modulation (s-s-b)

(B) Also could be set up by a keyed frequency shift (n-b-f-s)

Joint Usage Considerations

Power line carrier is used widely for services other than relaying, and most carrier relay schemes have certain provisions for limited nonrelaying usages. This paper will point out that these limited provisions lead to inefficient use of carrier energy and spectrum space, and have some hazards which are not recognized by all users. It would therefore seem desirable to examine the joint usage problem.

At present, with separate usages, economic compromise usually results in a communication channel which is not reliable when needed most, as in bad weather. At the same time, high grade equipment is used on relatively short distances to provide relaying channels which are in active use only a few seconds a year, while the nonrelaying usages tend to be frequent or continuous. (The economics of joint usage tend to become increasingly obvious as the number of needed functions increases.) These conditions point toward joint usage of carrier channels and equipment.

Carrier channels and equipment can be shared in varying degrees. Thus two or more functions, such as relaying and voice communication, might be combined, all utilizing the same frequencies and the same carrier receivers, transmitters, and so forth. These same functions might be combined by utilizing jointly the same "yard" equipment such as traps, coupling and tuning units, but using separate electronic equipment all on the same or separate carrier frequencies. Arrangements of the latter type would possibly

Paper 49-151, recommended by the AIEE Carrier Current Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer General Meeting, Swampscott, Mass., June 20–24, 1949. Manuscript submitted March 21, 1949; made available for printing April 28, 1949.

G. W. HAMPE is with the Relay Settings Section, and B. WADE STORER is with the Electronics and Communications Division, both with the Commonwealth Edison Company, Chicago, Ill.

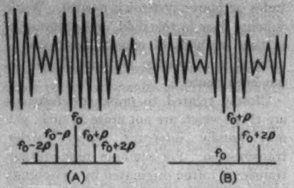

Figure 2. (A) Two methods of representing a carrier, amplitude modulated by two tones of frequency ρ and 2ρ are shown. (B) The modulation components remaining when the carrier and one side band have been suppressed are indicated

overcome special problems that sometimes arise, as in servicing equipment for unlike functions.

In general, every carrier application presents somewhat different requirements, and one form of joint usage or choice of apparatus is not necessarily the best solution to all problems. Hence it is necessary to study the various forms of carrier signals available, as to their particular advantages and limitations.

Carrier Channel Building Blocks

Carrier signals may be classified as to types of signal control or modulation or, the combination of the two. The direct form of control is that of keying the carrier frequency itself after the manner of a telegraph signal. Putting a carrier on (Figure 1) or taking it off, or both, is common in relaying practice. Keying, shifting a frequency, and coding the impulses produced by such controls also can be applied to carrier modulations. Descriptions of methods of transmitting modulated signals are given in subsequent paragraphs.

Carrier signals may be modulated in amplitude (a-m) after the pattern of the original form of broadcast radio. That is, the carrier frequency cycles may be compressed or enlarged in magnitude inside the envelope determined by the modulating frequency or set of modulating frequencies, Figure 2. The modulating frequencies are usually audio tones, that is, in or near the frequencies of audible sound. Such a signal at the receiving end is put through the process of detection, which is essentially rectification. This eliminates the carrier frequency, and the modulating (audio) frequency is reconstituted.

The modulating frequency also may be used to advance or retard the carrier waves in time phase. This is called phase modulation (p-m) as a general term. Since the changes of phase also are instantaneous changes of frequency, one form of phase modulation has been designated as frequency modulation (f-m). A frequency modulated signal when received is converted by a discriminator back to the original modulating signal.

When a carrier signal is modulated it tends to be spread over an appreciable portion of the carrier spectrum. This is true for all forms of modulation, not merely for f-m where it is obvious. (One special exception is indicated in Figure 1.) The resultant signal can be analyzed into the components which are the unmodulated carrier, and side frequencies, which, if modulation is done by a complex of frequencies, become side bands. The manner in which side bands originate can be found in several recent references.[4,5]

It can be seen that if carrier is modulated, the modulation as contained in at least one side band is essential. There are two variations of a-m which are intended to accentuate side-band energy. One involves the transmitter only, and is known as the Taylor[6] or "supermodulation" principle. In this system radio frequency power is supplied to the output circuit during the positive half of the modulation cycle by an auxiliary audio-pulse controlled power amplifier tube. Greater over-all efficiency with compressed carrier and emphasized side-band operation is claimed. In the second, one side band and the carrier are suppressed in the low energy stages of the transmitter, so that the entire transmitted energy is concentrated in one side band.[6] In the nomenclature of this and the sequel paper, the abbreviation s-s-b (single side band) indicates the suppression of both one side band and the carrier. For s-s-b the carrier must be reintroduced at the receiver as part of the process of detection.

For s-s-b, if a single modulating frequency is used, a single-side frequency is transmitted. The result, in wave form and frequency, is the same as if the carrier had been given a keyed shift, Figure 1. In Figure 2 complex modulation by two tones is shown for double side-band a-m, and the same with one side band and carrier suppressed as in s-s-b.

The modulating frequencies as well as the carrier itself can be keyed on and off. For f-m and a-m, the termination of all modulation restores unmodulated carrier. For s-s-b it terminates transmission.

A fourth carrier channel building block is equipment which operates on the narrow band frequency shift (n-b-f-s) principle. Here, instead of a modulation or an on-off keying, the carrier undergoes a keyed frequency shift. The frequency shift transmitter operates on such a narrow band that a number of such channels, each with its own transmitter and receiver, can be operated on line tuning and coupling equipment and traps which are tuned for one conventional broad-band carrier frequency.[7] The frequency shift is small, on the order of 60 cycles (on carrier of 100 kc). The receiver includes crystal filters and a discriminator, (f-m type, see Figure 3) and offers high selectivity with respect to spurious signals. It is stated in the foregoing reference that the spacing between these narrow channels, with frequencies stabilized by crystals need be only 0.5 per cent of the average carrier frequency. This applies to channels with the same direction of transmission. For transmission versus reception at the some terminal, the spacing required is stated to be approximately 5 per cent. Such transmission is useless for voice, but for other services, including some forms of relaying, it offers an alternative to audio tones superimposed on carrier.

Any of the foregoing principles may be used to transmit pulsed signals which may vary in frequency (pulsing rate), or which may be coded, that is, varied in amplitude, duration, spacing, or combinations of the foregoing to form code signals. Such pulses, pulsing rates, and pulse codes may be used for telemetering, supervisory control, and load control. All the forms of transmission are not equally adaptable to all uses, as the pulses may approach too closely to modulating frequencies, or be too rapid for the transitions required between states. As a rule, the narrower the spectrum in which the transmitted energy is confined, the more sluggish it is in changing states. This is a consequence of the energy stored and released by the filter elements. Given

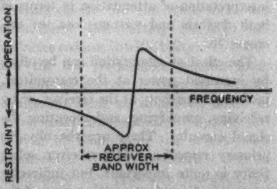

Figure 3. Characteristic of a discriminator (essentially an f-m type) as used for n-b-f-s signal reception

enough spectrum space, as in short-wave radio, even voice can be changed to coded pulses, transmitted as such, and changed back to voice[8,9] sounds. On a much slower basis similar principles might be used in the carrier field.

Carrier Channel Limitations

ATTENUATIONS

The energy impressed on a carrier transmission link is dissipated in various ways, so that the power at the receiving end is considerably less than at the sending end. This loss of energy or decrease of power is called attenuation. If there are irregularities of structure along the conductor paths, the response throughout the frequency spectrum may be quite irregular, limiting the choice of suitable frequencies. Sections of underground cable may have very high attenuation at all frequencies, but this varies considerably with the type of construction. For some types the means of bonding sheath sections is a critical factor. A paper on carrier attentuation measurements was recently presented.[10]

On some lines, particularly those with irregular frequency response, switching conditions may cause wide variations in attenuation. This indicates that in some cases terminal equipment beyond the line section has considerable bearing on carrier transmission—a factor which will be reconsidered in regard to the application of traps. If the extraneous influences are coupled to the line by other wires on the same right-of-way, the choice of a suitable frequency to meet all contingencies may involve a considerable number of test measurements.

Bad weather conditions, such as ice formation, greatly increase attenuation at a time when good relaying and communication are at a premium. Dirty insulators combined with fog, rain, or ice also may cause increased attenuation. The attenuation, as a function of the ratio of transmitted to received power, is expressed usually in decibels.[21] For an interpretation of attenuation in terms of both decibels and wattage loss, see reference 10.

The effect of attenuation can be offset by increased power at the transmitter, increased sensitivity at the receiver, or by receiving, amplifying, and repeating the signal enroute. These are the obvious primary remedies. The receiver selectivity is quite important, but indirectly so, as it is dependent on the nature of the desired signal. This is discussed in detail later. The amount of attenuation can be reduced by other means, such as changing the route of transmission, the frequency of the carrier, the form of coupling, and so forth.

For voice transmission over longer distances, the joint usage of relay channels may be made practical by the use of audio by-passes at intermediate switching stations. Audio by-passes introduce distortion, however, so that the number of links that can be thus placed in tandem is limited. Such by-passes, by reception and repeated transmission into the succeeding line section, make the amplification of the nonrelaying (communication) signals possible. This large gain in signal strength makes practical transmission over much greater distances. Such by-passes are essentially independent of switching conditions, probably to a greater degree than conventional by-passes on yard equipment, and further permit passing the through-type communication signal on to a succeeding carrier relay channel.

SIGNAL VERSUS INTERFERENCES

The principal limitation on receiver sensitivity is that type of interference known generally as noise. Noise, which for present purposes is not defined as being limited to audible range, may be fairly constant for appreciable time intervals (that due to corona for example), or may come in random pulses, or be tied in, more or less predictably, with reproducible phenomena on the line or in its proximity. In interpreting the effects of noise, it is often combined with signal strength values and referred to as the signal-noise ratio. Some functions can tolerate a lower signal noise ratio than others. Although the transmitters and receivers for communication and conventional relay carrier are similar, the communication receiver can usually be adapted to work through a greater attenuation than the relay signal, hence the latter channel must be limited in attenuation or bolstered to meet relay standards. Under average conditions this is logical, as signals too weak or too noise-ridden for relaying may be quite intelligible to experienced personnel. In bad weather when communication is at a premium, the weak and noisy signals become worse, which may be unfair to those depending on them under those conditions. The signal-noise ratio can fall off due to increased attenuation, increased noise, or both, and during bad weather conditions both limiting factors usually become worse, and a simple listening test is not a very reliable indication as to which effect predominates. Greater knowledge of signal-to-noise ratios, and of noise amplitudes on power systems is needed. Work is being done in this field, and progress in getting methods of measurement standardized into readily comparable forms has been made.[11]

Closely related to noise interferences are those which are not noise as such, yet may totally interrupt proper carrier transmission. For example, high-voltage transients (often originated by switching) may flashover safety devices on the carrier apparatus. Interference also may take the form of spurious signals which are essentially indistinguishable from the functional ones. Total signal suppression and spurious signals may result from the same or similar causes.

This brings up a very interesting and important observation. One would expect that fault arcs might set up spurious signals. This they probably do, but experience and staged fault tests indicate that sufficient spurious signal to interfere with relaying is quite rare.

Circuit breaker arcs have been observed to cause considerable interference, and the question arises as to whether automatic circuit breaker operations on one line can suppress (or falsely initiate) signals on an adjacent line. Further evidence on this point should be gathered. One manufacturer has provided relay circuit controls for over-riding a transient of this type. Experience indicates that the most pronounced interferences, both as to suppression of signal and spurious signal, result from low-power arcs in circuit breakers and on disconnect switches in, and adjacent to, carrier terminals.

Signal transmission may be interrupted by short circuits or open circuits on the transmission line. Just what constitutes an effective short circuit or open circuit is questionable, however, where carrier is concerned. The deliberate use of alternate paths has been proposed.[12]

AVAILABILITY OF CHANNEL SPACE

Another class of interferences might be likened to the problem of cross-talk in the field of audio communication over metallic channels. In a given locality the carrier spectrum (bearing in mind that some frequencies may be found unusable because of excess attenuation) often rapidly becomes congested. Each power line is of course closely coupled to the other lines paralleling its path so that frequency separation is necessary. Interference with other line sections is limited by geographical distance and frequency separation, that is, by keeping adjacent frequencies at remote parts of the power system. In special cases, more expensive arrangements, such as trapping every phase of every line beyond a certain bus, may be found expedient. There also are interferences with respect to other power companies and other utilities outside the field of electric service.

It was mentioned before that receiver selectivity is an important factor in limiting interference from random noise. With regard to adjacent channel interference it is even more important. The narrower the acceptance band of the receiver, the less interference it will pick up, and, other things being equal, the closer it can be placed to its neighbors, both in geographical and spectrum space.[20] The acceptance band width will depend on the nature and content of the transmitted signal, and will in general tend to be at least somewhat wider than that covered by the signal. This is due in part to the need for some tolerance in regard to the stability of transmitting and receiving equipment, and partly due to the inherent nature of reception. For example, for some applications there is monofrequency transmission, but there is no way of providing reception that will accept only one frequency. Furthermore, an acceptance band whether narrow or wide, Figure 4, never has perfectly straight sides, hence signals of considerable frequency deviation will be received if they are strong enough. This puts a considerable handicap on close spectrum spacing of a receiver and transmitter at the same terminal.

The f-m discriminator used with the n-b-f-s receiver has a characteristic as shown in Figure 3. It offers a sharp and stabilized point in the frequency spectrum at which the carrier crosses over from restraint to operation and vice versa, hence the narrow band effect is accentuated. Noise covers a wide band, in general, hence cancels itself in the discriminator circuit. Adjacent channel interference may be limited considerably by crystal filters, but placing the n-b-f-s channel so that adjacent carrier tends to produce restraint may be an added factor of safety.

For a-m, f-m, or s-s-b a wide band tone receiver can be used to provide restraint if spurious signals are received. In one proposal[15] everything (so far as practical) outside the narrow band required for the desired signal is to be received and applied through appropriate circuits as a restraint.

Another principle in guarding against interference is to transmit a continuous nonoperating or restraint signal which must be removed or shifted before an operation can be transmitted. By automatic volume control action, such a restraint signal reduces the sensitivity of the receiver to noise and unwanted signals, in addition to whatever direct holding effect the signal provides. The objection is that a continuous transmission of carrier, or a tone modulation thereof, furnishes a constant source of possible interference. This applies both as to the fundamental transmitted frequency and possible harmonics. In some cases a constant source may be worse than an intermittent one as regards other channels. It is questionable whether this is really a valid objection, and data are needed to substantiate it. In other applications provision is made for reception of a restraint signal, but it is deliberately transmitted only when conditions become abnormal.

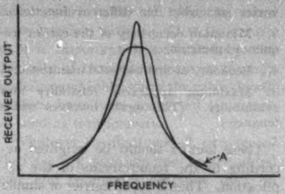

Figure 4. A typical acceptance band of a receiver

A signal impressed at A, if sufficiently strong, will cause interference

For any type of carrier transmission the acceptance band of the receiver should fit the transmitted signal fairly closely, but in trying to cover a variety of standard applications with a minimum variety of apparatus, this is not consistently followed. For example much relaying is done with a monofrequency, keyed carrier, but the receiver is wide band. This permits reception of the side bands which are added to the carrier when test or emergency communication is used, but the receiver also is wide open for noise and for interference from other signals. If a narrow-band receiver were used for relaying, transmitters of present wattage ratings would provide for operation through considerably increased attenuation ranges. If the transmitter wattage should be reduced to cover any but the most exceptional conditions, more relay channels could be fitted into a given spectrum space, both because of increased discrimination against unwanted signals, and the reduction in power of those signals.

For example, if there are four carrier relay channels between two terminals, test and emergency communication is hardly necessary for all of them. Similar logic applies where specific provision for communication has been made. Note that if the relay carrier receiver band can be narrowed only moderately, as for phase comparison relaying, the foregoing still applies, but to a reduced extent. Other considerations may outweigh the saving in spectrum space, and other adaptations, as offered in the second paper, may be more advantageous.

Carrier channels normally operate at frequencies between 50 and 150 kc, with the band between 150 and 300 kc being used mainly because of congestion in the lower band. The higher frequencies will tolerate a more rapid keying or pulsing rate, which is an advantage, but the carrier attenuation tends to be somewhat greater than for the lower band.

DISTORTION

Transmission also is limited by signal distortion, that is, by differences in quality of the input and received signal existing even in the absence of extraneous disturbance. When the signal is produced by keying carrier the transients of the apparatus, which determine the time required for the carrier to go from one steady state to another, are the principal distortion. The same type of distortion occurs when an audio tone is keyed. If an audio tone is keyed at a rate approaching its own frequency, distortion of signal naturally results.

Audio tones, including the voice frequencies, are subject to harmonic distortion, frequency distortion, phase distortion (usually not serious) and cross modulation. All of these forms tend to originate from, or be augmented by, the nonlinear characteristics of carrier apparatus. Such nonlinearities may be the result of imperfections or deliberate design. For example, a flat frequency characteristic from 200 to 3,000 cycles is considered necessary if voice is to be transmitted naturally and intelligibly. Cutting off the low end tends to reduce naturalness, but cutting the high frequencies reduces intelligibility. To transmit the low frequencies requires large amounts of energy, tending to overload equipment such as amplifiers, hence in some cases intelligibility may be improved by eliminating the lowest voice frequencies. This is particularly true on equipment not primarily designed for communication. It is a matter of general observation that test and emergency communication over carrier relay channels is usually better on the lines with weaker signals, as strong signals saturate the receiving apparatus.

Another cause of distortion is overmodulation. For amplitude modulation including single side band, this means the modulating tone or combination of tones is more than sufficient to bring the carrier wave down to zero amplitude. The "super-modulation" principle is an interesting attack on this problem.[6] For f-m transmission, over-modulation means a frequency shift beyond the channel width for which the equipment is designed. For any conventional type of modulation it is evident that elimination of portions of the low audio spectrum, which involve high energy levels, tends to prevent that form of distortion which results from overloading and overmodulation.

Cross modulation arises in various ways, but becomes a particular problem when part of the audio spectrum is set aside for tone signals, as for telephone ringing or for relaying. To avoid it, audio tones which exist simultaneously must not have frequencies which when added or subtracted will give rise to tones where they are not wanted, in the voice band for example. This becomes an interference problem.

Another source of distortion as well as loss of signal strength may be apparatus instability, that is, the tendency of the apparatus components to drift out of line with age or changing atmospheric conditions. This involves problems of detail design and maintenance.

Choice of Carrier Channel Building Blocks

At present, the available carrier channel building blocks are: (1) keyed carrier, (2) modulations transmitted by (a) conventional (a-m) (with "super-modulation" as a possible variation), (b) single side band, (c) frequency modulation, and (3) the narrow band frequency shift. Each has distinctive properties which should be considered for a given set of functions in a given installation. Combining functions in joint usage in varying degrees gives quite a variety of possible combinations, and it is quite possible that more than one building block can be used to an advantage.

The choice of building blocks should be guided according to the following factors:

1. Suitability for the desired function. (There are usually several means of obtaining the same result.)
2. Operating range sufficient to work through the maximum attenuation and interferences. (The pressure in this respect varies somewhat for different functions.)
3. Minimum occupancy of the carrier frequency spectrum.
4. Economy of first cost and maintenance.
5. Maximum apparatus reliability and availability. (This again involves maintenance.)

These factors should be weighted according to the requirements of the application. Thus if keyed carrier or simple a-m will suffice, that is what should be used. Unfortunately, particularly in regard to line characteristics, the necessary data are often lacking, so that an installation may prove to be inadequate in use, or may be made much more than adequate at excess cost, to allow for unknown factors. To avoid misapplications sufficient test data should be taken in advance.

SPECIAL PROPERTIES

Some special properties have already been discussed under the limiting factors of attenuation, noise, cross-talk, and distortion, but there are others which were not emphasized. Thus n-b-f-s can be used for telemetering, and so forth, and some kinds of relaying. It cannot be used for communication, but can be superposed on an a-m communication channel.[7] The s-s-b type of transmission makes possible a minimum acceptance band for voice. As an example of limited joint usage, n-b-f-s could share common yard equipment with s-s-b. The n-b-f-s channels can be placed in the spectrum space on either side of the s-s-b signal.

Conventional a-m and f-m occupy approximately twice the channel width of s-s-b. Where channel width is not a final determining factor, it should be pointed out that f-m transmission (with limiters to eliminate amplitude variations) provides an excellent automatic volume control characteristic that is quite advantageous.

There are many carrier applications where it is desired to accomplish a number of separate functions such as transferred tripping, load control, and so forth. These functions may be accomplished by either tone modulations of a-m, f-m, or s-s-b transmitters or by n-b-f-s transmissions, with possible pulse coding in any case for greater adaptability. A tone carries only a portion of the total energy of the modulated carrier, but it also picks up only a portion of the total interference suffered by that carrier, hence, within limits, tone signals are quite reliable. The greater the number of simultaneous tones, the more the total signal energy must be subdivided. With n-b-f-s channels there is a similar limitation. The greater the number of n-b-f-s channels using common yard equipment at a given terminal, and transmitting signals simultaneously in a given direction, the less the range of each.[7]

For reasons stated previously, the present-day relay practice of using a wide band carrier channel exclusively to transmit a simple on-off signal will in the future meet increasing resistance from economic considerations and spectrum crowding.

Terminal Equipment

Carrier transmitters and receivers are coupled to the power line by capacitors connected between one phase conductor and ground, or between two phase conductors of the same 3-phase circuit (interphase coupling) or between two conductors on different circuits (intercircuit coupling). The same equipment may be used jointly for separate channels on more than one type of coupling. For example, the coupling capacitors (and traps) of two conductors coupled to ground on two circuits with the same station destinations also may be used for intercircuit coupling by the addition of line tuning units for added frequencies.

One advantage of interphase, or better still, intercircuit coupling is that certain types of line work can be done without interrupting the channel. Also it is claimed that the channel can be balanced so as to minimize interference to and from it. The counterclaim is that this balance is too hard to maintain to have any practical value. For some types of relaying, phase-to-ground coupling is not considered acceptable as will be discussed in the second paper. The disadvantages of interphase or intercircuit coupling are greater cost (unless in combination as above) and increased coupling loss (attenuation). The coupling loss is generally a minor factor however.

By the introduction into the power line conductor of an inductance in parallel with a capacitor, a carrier frequency or a band of frequencies with a spread of up to about 12 per cent can be substantially prevented from passing a certain point in that conductor.[18] Such devices are called traps, and may be tuned to block more than one frequency band. Tuning one trap to resonate for more than two frequencies is considered highly impractical, however.

Carrier for relaying is usually blocked by a trap at the end from which a signal is to be transmitted, so that the signal is projected, initially at least, in only one direction. The trap can be omitted if some other device such as a power transformer serves the same purposes, or if 2-way projection is admissible. The principal purpose of trapping relay carrier is to prevent the transmission of carrier energy from being short circuited or seriously attenuated by a fault or switching condition exterior to the protected line at the transmitting terminal. If intercircuit coupling is so arranged that no fault or special system operating setup can reduce the carrier energy to an unsafe level, trapping may be omitted in some cases. Also, if a signal is only received at a terminal, trapping for that signal at that terminal may not be necessary. A trap that is tuned for one or two frequencies offers considerable impedance to other frequencies, particularly the adjacent ones in the spectrum. Often a dead short circuit beyond a protected line section would still leave sufficient signal transmission for satisfactory relaying because a trap that is not resonant to a certain frequency still offers considerable impedance. For relaying, this is not often trusted, however, because the off-resonance value of a trap is either inductive or capacitive, and there may be some condition beyond the line terminal which will reduce the effective value of that inductance or capacitance to practically zero. In particular cases, as when the trap is backed up by a piece of power apparatus that blocks all frequencies, operating more than one frequency on a single tuned trap may be just as efficient as double tuning, or when compared to coupling to additional phases, there may be considerable economy. Limited trapping should be considered for minimum cost installations on low-voltage lines.

The other functions of trapping are to decrease attenuation by largely confining signal energy to a given line section, and to decrease the cross-talk type of interference with other carrier channels. In some exceptional cases all three conductors of a line (sending or receiving or both) may be trapped, as the natural coupling between phase wires tends to put the signal on to conductors from which it can propagate into other sections. How effective this is depends on what other conductors are on the same right-of-way or adjacent to it (and for what distance), and how much is propagated over static wires.

Whether multiconductor trapping with phase-to-ground coupling decreases the effectiveness of transmission is at present disputed. It has been stated that the noncoupled conductors, in parallel with the earth and static wire, form part of the signal return path, and that the extra traps interfere with it. That the return path is important is evidenced by the difficulty of transmitting carrier through underground cable where the cable sheath sections have been connected by means of bonding transformers.

Whatever the final answer on some of the foregoing questions may be, the added care and equipment generally used on relay carrier channels, as compared to carrier channels for other services, becomes available to increase the reliability of those services under joint usage.

Performance Requirements

Power line carrier performance requirements may be classified into three groups according to functions, as relaying, communication, and miscellaneous services.

CARRIER RELAYING

Relaying by carrier requires a high degree of transmission reliability and availability. This means a good received signal even under adverse conditions and means of readily checking and maintaining the over-all carrier and relay performance. Other things being equal, carrier relay equipment which can be checked and maintained independently of the noncarrier relay elements (which may be either first line or back-up relay elements) is preferable. With respect to joint use of carrier relaying equipment for nonrelaying purposes, there are advantages and disadvantages. As most of the other services are constantly in use they automatically monitor the carrier equipment which otherwise functions only during system disturbances.

Maintenance of a jointly-used carrier channel may run into difficulties where separate groups of personnel, communication and relay sections of the same organization, for example, are both handling carrier transmission equipment. Fundamentally there is little difference in this equipment whether it be for relay carrier or communication carrier. Since power line carrier is a highly specialized field it would seem that the simplest solution to this maintenance problem would be to have a separate carrier section responsible for all types of carrier equipments. If such an arrangement cannot be worked out, the problem must be recognized, and the carrier equipment for joint use be laid out so that the functions may be separated satisfactorily. In some cases separation of the functions into separate cabinets is a satisfactory solution for maintenance under divided authority with joint usage.

CARRIER COMMUNICATION

Communication by carrier can be classified into three functional grades. The lowest is for testing and emergencies. The next is for operating, that is, switching orders, load dispatching, and possibly work dispatching. This calls for a high degree of reliability and availability, quite similar to that for relaying, but high voice quality (for example, personal voice recognition) is not so essential. It is surprising how much distortion and noise can be tolerated by experienced personnel. The highest grade is administrative communication, which in addition to high reliability and availability needs fairly good tone quality. Those who use the channels regularly will accept distortions which others will not. Good quality requires a band 2,500 to 3,000 cycles wide, hence uses a considerable slice of the carrier spectrum.

Communication also may be classified as point-to-point, push-to-talk, party-line, selective ringing, duplex, and so forth, which are not all equally suitable for the three functional grades mentioned before. Signaling (as by tones) is required for some of the above functions.

MISCELLANEOUS SERVICES

The miscellaneous services follow:

Glaze (ice) Detection. This is essentially a by-product of received signal strength measurements, but may justify equipment designed for the purpose.

Supervisory Control. This includes remote control of switching and remote indications of system conditions—usually on an on-off or alarm basis. It is accomplished usually by coded signals. High reliability is desirable, but the signals are merely keyed pulses.[19]

Automatic or Semiautomatic Load Control. This is similar to supervisory control, but reliability under adverse conditions is not at a high premium.

Telemetering. Next to voice and some forms of relaying this may be the hardest form of signal to transmit, but reliability requirements are much like those for load control.

A Fundamental Relay Control Problem with Joint Usage of a Single Signal

TYPES OF CARRIER RELAYING

There are at present three standard types of carrier relaying. These are:

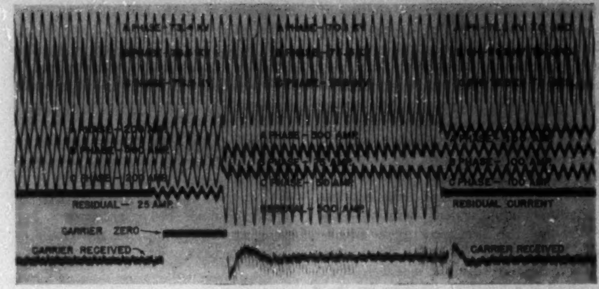

Figure 5. A record of a fault in which relay control of carrier was lost when the line opened at one end

(a) transferred tripping; (b) directional comparison; and (c) phase comparison.

Type (a) is usually used to protect terminal apparatus.[3] It is limited to special cases and is not often combined with types (b) and (c). A continuous carrier blocking tone is sometimes used to prevent false trip-outs. To date, the most important applications of (a) have been on two terminal lines, but multiterminal applications show promise.

In types (b) and (c) carrier signals are not normally transmitted continuously for relaying. Standard relay equipment provides for the use, or ready adaptation, of the carrier frequency for test and emergency communication and for keyed signal functions such as telemetering. One disadvantage in having relay carrier (or a tone) held on for relaying or any other purpose, such as signal strength tests, or measurements for sleet detection, is that on-off control of the signal by relay elements must be provided at both terminals when a fault occurs.[16]

If at a given terminal there is a firm source of fault current, present equipment is designed to accomplish this purpose. If there is no fault current source for a terminal, or if the path of that fault current is interrupted, there are no standard provisions for the relay elements to secure control. With the types (b) and (c) if a steady signal is transmitted (as under joint usage) from a terminal which does not supply fault current, carrier relaying at the terminal which does supply fault current is suspended.

The cases in which no effective fault current can flow from a given terminal are as follows:

1. No source of positive phase sequence current. The failure to open where there is no source is not generally serious, but the carrier restraint at the supply end may be objectionable. Generally noncarrier relays must function at the source terminal.

2. A feeble or transient positive sequence current source. If there is no immediate automatic reclosure, this may be viewed the same as (1), but with such reclosure, immediate opening at both ends may be required to prevent the feeble source, motor regeneration for example, from sustaining an arc which would cause retripping.

3. A positive sequence source, but no effective source of zero sequence current at a terminal. In this case a fault to ground (even though cleared from one end by noncarrier relays) may lead to continued abnormal voltage stresses, possibly augmented by an arcing ground at the point of fault.

4. The circuit breaker being initially open, or open pending automatic reclosure. During glaze storms lines may be open at one end for several minutes, and occasionally, to shift load to other lines for glaze prevention, single end excitation (called "holding a line alive on back feed") may extend to hours.

5. Sequential operations. Occasionally, because of system or fault conditions, a line opens quickly at one end only. The open end relays then have lost control of the carrier, and the remaining end is still to be opened, Figure 5.

6. A breakage of one or more phase conductors. This interrupts the path of the fault current from one terminal in many instances.

An Example of Loss of Relay Control

The oscillogram of Figure 5 shows an example of (5). Carrier had been placed on at the remote terminal for glaze detection and was received as shown on the oscillograph trace. A fault-to-ground occurred and the remote end circuit breaker opened promptly from the instantaneous (noncarrier) ground relay. For unexplained reasons the local end did not furnish enough ground current to actuate the carrier control relays. The received carrier ceased momentarily, but as soon as the remote circuit breaker opened the carrier stopping relay at that end reset and carrier was again transmitted from the remote terminal and received as shown. The local circuit breaker would have been opened by the ground backup relay, but meanwhile the arc extinguished of its own accord as shown by the neutral current trace. The local circuit breaker did not open.

The same difficulties can be encountered if carrier is transmitted from the no-source end for telemetering, communication, or even push-button tests. Inquiries have revealed that in some utilities that use carrier for relaying, this aspect of joint usage on standard equipment is not recognized, or at least not fully evaluated.

If deliberate, not incidental, joint usages of carrier relay channels become common, as economics and spectrum crowding already dictate, the problems of relay control must be solved so that carrier relaying is not handicapped under any system conditions. Solutions of this fundamental carrier control problem under joint usage will be presented in the second paper.

Summary

1. Carrier relaying according to the present practice, or the equivalent, is needed, particularly, but not exclusively, for ground faults, and will be increasingly needed with adaptations for automatic reclosing and multiterminal lines.

2. Joint usages, which may be adopted in various degrees, will alleviate spectrum crowding, and for many installations such usages will provide either reductions in installation and maintenance costs, or improved performance, or both.

3. Various types of carrier control and modulation are available.

4. The problems of carrier transmission and reception can be discussed qualitatively, but quantitative knowledge is meager.

5. In comparing carrier types or systems there are distinctive characteristics in each, both as to function and performance, which may be advantageous.

6. The choice between the available systems will depend largely on the functional characteristics desired, but it appears that there are undeveloped potentialities in each, and possibilities of making combinations.

7. The nonrelay usages vary in their requirements, making each application a distinct problem.

8. Present standard relaying equipment provides for limited joint usages of a single carrier signal with possible consequences which do not seem to be generally recognized, namely, the wide receiver acceptance band, with corresponding inefficient use of carrier energy and spectrum space, and in-

complete carrier control by primary relays.

9. Carrier relaying needs to evolve to meet new problems. Suggestions along that line, including solutions to the primary relay control problem, will be offered in the second paper.

Discussion

C. E. Asbury (The Commonwealth and Southern Corporation, Jackson, Mich.): This paper gives quite a complete outline of the present-day equipment available, conventional methods of application and summarizes the present problems and limitations of carrier relay applications.

We agree with the authors that there is need for evolution in present-day carrier usage which will extend its application and usefulness. These developments should extend carrier relaying for protection of modern systems being built up to include multiterminal lines, lines supplying tap loads and lines terminated in transformer banks without high-voltage circuit breakers.

One of the major factors leading to joint usage of carrier channels is that of economics. Most of this joint usage is brought about in order to justify the installation of the carrier relay equipment and is not chosen just to accommodate other services. Much of the cost of a carrier installation is in the terminal equipment, such as coupling capacitors and wave traps. If these devices could be eliminated and a more economical method found to perform their functions, it is quite probable that there would be much less need for joint usage especially on carrier relay channels. There are a number of disadvantages of joint usage on carrier relay channels when using present-day practices. The authors apparently have studied all of these various objections and plan to outline methods of solution in their following paper on the subject. Such information should be helpful and welcomed by the industry. Some of the problems that need to be considered are:

1. Any additional equipment which may key the carrier is likely to block carrier relaying with that line terminal open when the line is being tested from the opposite end. It is not always desirable to block these additional functions while the circuit breakers are open. This loss of relaying control is very undesirable, and some provision should be made to avoid it where joint usage of carrier relay channels is to be utilized.

2. In a number of applications, joint usage is made of the coupling capacitors and occasionally of the wave traps. Such joint use results in the installation of filters to block one carrier frequency from the other. Not only are these filters expensive, but they complicate the maintenance of the equipment and are a potential source of trouble due to failure or possible shifting of frequency, requiring frequent checks on tuning.

3. Additional functions often are performed over a given carrier relaying channel by the use of audio tone equipment. Where such applications are used, it is necessary that provisions be made to avoid the loss of relay control, especially for conditions of one circuit breaker being open. The amount of carrier energy available for each tone channel is reduced as the number of tones is increased. Thus there is a limitation as to the decibel range of such equipment and to the number of tones that may be applied successfully.

4. There is a limitation to the number of frequencies that may be passed through a given coupling capacitor. Usually no more than two such frequencies can be utilized successfully on one coupling capacitor where amplitude modulation equipment, such as carrier relaying, is utilized.

It appears that considerable advantage could be realized in carrier current relay applications if the band width occupied in the frequency spectrum could be reduced. With present design carrier relay sets, it usually is considered necessary to separate frequencies on adjacent lines or on parallel lines by as much as 15 to 20 per cent. It is interesting to note that crystal control transmitters are available for metering; 15 or 20 of these channels can be worked successfully through a coupling capacitor. The decibel range of these metering carrier equipments is approximately two times that of the conventional carrier used for relaying and yet the cost of carrier relaying transmitters and receivers is approximately twice as much as that of the metering equipments.

Even with the present broad-band frequency required for carrier relaying and communication, little real difficulty is experienced with interference between channels. Regional committees have been appointed by various power groups to study and to assign frequencies in the regions to avoid interference. However, there is a dire need for 150–300 kc frequency band to extend the use of power line carrier equipment. With continued co-operation among the power companies in wisely utilizing the frequencies available in the 50–300 kc band for metering communication, supervisory control, relaying, and other similar functions, it is believed that with the continued co-operation of the carrier current equipment manufacturers in reducing the amount of frequency spectrum required per channel that little difficulty should be experienced due to interference between channels for the next several years. In the application of carrier relaying, it usually is possible to utilize the same frequency for a number of channels since each channel is trapped. Usually one intervening line section operating on a different frequency is all that is required for proper separation of lines having carrier relay channels operating at the same frequency.

H. W. Lensner (Westinghouse Electric Corporation, Newark, N. J.): In the development of power line carrier equipment for relaying, simplicity always has been one of the main factors. The transmitter usually is a conventional oscillator-amplifier combination using a stable oscillator which is adjustable over the carrier-frequency band. The amplifier increases the output power to a reasonable level. The relaying receiver has been kept as simple as possible consistent with good engineering practice. More than 20 years of experience has shown that a transmitter-receiver combination capable of working through an attenuation of 30 decibels is satisfactory for very nearly all carrier relaying applications. A 10-watt transmitter and a single tube receiver will provide this operating range, which is sufficient for most overhead line sections.

A single tube receiver will have a response curve several kilocycles wide, but its limited sensitivity makes it possible to use a frequency only a few kilocycles away at a remote point on the power system without interference. A more selective receiver will of necessity be more complex, and if the transmitted power is reduced to lessen interference in other channels, the increased sensitivity of the receiver makes it more susceptible to line noise, although this may be somewhat offset by the increased selectivity. Up to the present time, the simple relaying receiver has been adequate, but with the limited frequency spectrum available, the increased use of carrier in the future well may require the use of more selective receivers.

One subject briefly discussed in the paper is the unfortunate situation (which usually exists) that line characteristics are often lacking in the negotiation stage of a carrier application. This lack of information is a great handicap, particularly in considering a carrier communication channel running through several hundred miles of power lines with their taps, busses, parallel lines, and re-entrant circuits. It would be very desirable to have frequency-attenuation data on a power system in advance of the purchase and installation of suitable equipment. Such data would be of value to the manufacturer in determining what equipment was necessary, and to the user in putting the channel in operation. Unfortunately, in most cases suitable test apparatus is not available, and it is necessary to wait until the equipment is installed to check the characteristics of the power system. At the present time, there is no known method of calculating with any degree of accuracy the frequency-attenuation relation of a complex power network, so field tests are necessary to obtain this information which is needed to assure a dependable channel with various conditions of weather and system switching.

Another subject discussed is the carrier relaying of a line in which no effective fault current can flow from one terminal. When such a condition exists, some means must be provided at that terminal for on-off control of the carrier signal, so that if a fault occurs during communication, proper relaying can take place. The requirement has been met in several installations by using high-speed undervoltage relays, with their contacts in the communication carrier-start circuit. Upon the occurrence of an internal fault, at least one of the undervoltage elements will drop out, thus stopping carrier and allowing the other terminal to trip. An extension of this idea has been used to provide high-speed tripping of both ends of a line section with little or no source of fault current at one end. A continuous carrier signal is transmitted from the terminal which has a firm source of fault current. At the opposite terminal, the received carrier signal energizes a relay element to hold its contact open. This contact is in series with the paralleled contacts of three undervoltage elements to complete the trip circuit. Upon the occurrence of an internal fault, carrier is stopped by normal relay operation at the terminal with a firm source, and the loss of carrier plus a reduction in voltage on at least one phase completes the trip circuit at the opposite terminal. While this system requires a continuous carrier signal, it does solve a rather difficult relaying problem and allows the use of normal carrier relays at both line terminals with a few additional relay elements to provide complete protection.

G. W. Hampe and **B. Wade Storer:** We agree readily with Mr. Lensner's desire to keep power line carrier equipment as simple as practical. Compared with some equipment designed to compete with power line carrier, it is simplicity itself.

Specifically, where a wide band receiver and a transmitter in a combination capable of working through 30 decibels is satisfactory, that is what should be used. There have been and probably will be a number of lines where the application is not in question.

However, our present knowledge of the effect of weather conditions and line irregularities, such as taps and cable sections, is meager. The makeup of some present line installations is such that the attenuations and noise levels are high normally and go still higher under abnormal conditions. The newer lines, and the older lines with added taps, need high standard relaying, such as only carrier can offer at the present stage of the art. Thus we find ourselves attempting to solve carrier problems of progressively increasing difficulty. One of our several needs is for increased operating ranges, in which is included a good signal-to-noise ratio.

One way to improve this situation seems to be to increase receiver selectivity. This fortunately falls in line with the need for conserving spectrum space, as Mr. Lensner agrees. Considering the great improvements in receiver component parts made possible during and since the war, a more complex receiver may well be more reliable than the present ones.

Mr. Lensner mentioned the handicap of not having beforehand knowledge of transmission characteristics on long communication channels. The AIEE Carrier Committee is gathering data which should be of substantial benefit in such cases. The writers question, however, whether long hauls at a single carrier frequency are really necessary. Under joint usage the problem can be simplified. By utilizing the well trapped carrier relay channels with repeater points at the ends of the line sections, the effects of attenuation and varying system operating conditions can be greatly reduced. The repeater points can use audio by-passes, provided the number in tandem is not excessive. An application of this type, with one audio by-pass, is now in service on the Commonwealth Edison System, and a second application using two such by-passes has been planned for future use.

Another similar solution has been proposed which would use a nondemodulating carrier repeater (so called for lack of better name). This would repeat the communication signal at a different carrier frequency in the next line section without descending to the audio-frequency level.

In reference to the use of undervoltage relays to remove auxiliary services during fault conditions:

This is quite feasible in some applications, but to do so for the open circuit breaker condition requires an adequate set of potential transformers or potential devices on the line itself. In many cases bus, not line, potential transformers are used. In such cases there may be only a single-phase potential device for synchronizing and back-feed indication. In other cases, the line potential transformers are "VV" connected, and their secondary output gives no clear-cut indication of the existence of a single line-to-ground fault.

If the auxiliary services are at all important, it is desirable to continue them past an open circuit breaker or even with the line dead. This means that an additional device, such as a fixed time relay, must be used to restore the auxiliary services. It would be desirable to have a solution to the control problem which would be more generally applicable and simpler. One should not lose sight of the voltage variation principle in setting up carrier relay schemes, however, as Mr. Lensner indicates.

Mr. Asbury indicates that much of the cost of a carrier installation is in the terminal equipment such as coupling capacitors and traps. There is no generally accepted way of dispensing with the coupling capacitor, but it can, of course, be used jointly for various services.

In regard to trap requirements it is necessary to consider the type and location of the line itself, the attenuation and interference problem, and the number and nature of the desired services. On trunk lines, for example, adequate trapping is essential. Economies in trapping should be obtained, not by eliminating traps, but by making greater use of each trap that is required. For example a wide band of frequencies might be trapped by utilizing the trap as a band elimination filter. Likewise, utilization of the coupling capacitor as a wide band-pass filter will provide joint usage with the resulting economies that both the authors and Mr. Asbury feel are necessary. A proposal covering this use of traps and coupling capacitors is presented in a paper scheduled for the AIEE Pacific General Meeting.[1]

On subtransmission lines there may be few desired services other than relaying, and costs must be cut. Traps should be used sparingly. Just how sparingly depends largely on the interference and attenuation problems.

In restating the problems presented in our paper, Mr. Asbury also mentioned cost and maintenance difficulties of filters. To the extent that we have dealt with filters to date, we have found them simple to maintain and quite stable. The objection should be made more explicit.

Mr. Asbury points out that the power companies have generally worked out their interference problems. He states that they can continue to do so, if the band now available between 50 and 300 kc is used. To this we heartily agree.

Mr. Asbury also agreed to the main premise of our paper, which was that power line carrier needs to evolve to extend its application and usefulness. From the relaying standpoint, this includes protection for multiterminal lines, lines supplying tap loads, and lines terminating without high-voltage circuit breakers. The factor of immediate automatic reclosing should be included.

Relaying of Transmission Lines from the New Sunbury Generating Station

H. H. GREEN
NONMEMBER AIEE

J. A. G. OEWEL
MEMBER AIEE

O. RAMSAUR
MEMBER AIEE

IN PLANNING the development of the transmission facilities needed for the output of the new Sunbury plant of Pennsylvania Power and Light Company, provision of spare lines has been avoided by placing full dependence on the ability of modern line protective and restorative relaying to reduce to short durations all outages except those caused by relatively rare persistent faults. As a result, the number of lines is being held to those already in existence in close proximity and those required for carrying capacity to certain regional loads.

This paper deals with the functional requirements of relaying in the development of the transmission outlet for the initial 150-megawatt installation at Sunbury, some of the special problems encountered, and the kinds of relaying selected to meet these requirements and to solve these problems. Circuit and elementary diagrams are omitted, on the assumption that relay engineers are familiar with the common types of protective and reclosing relay methods being used.

A brief discussion of the new generating station and the transmission system will provide background for the discussion on relaying.

The New Plant

The new plant is situated on the west bank of the Susquehanna River, about two miles below Sunbury, Pa. The site was acquired many years ago because of its central location in the western part of the system, which was the logical point of the next large power source, and because of the availability of sufficient water, proximity of fuel sources, and so forth. Its ultimate installation has been kept continually in mind in the planning of all new major facilities in that vicinity.

The initial installation comprises two 75,000-kw units, each connected through a 13.8–69-kv step-up transformer bank directly to one of the two sections of the 66-kv double bus, as indicated schematically in Figure 1. These first two units are expected to go in regular service in 1949. A third unit of 100,000-kw capacity is already under way, to be completed in 1951.

Transmission System

The major transmission system is shown in map form in Figure 2. Basically, it consists of a 66-kv network which is fed at dispersed points by generating stations of various sizes, a 220-kv interconnection, and several 66-kv interconnections. Transformer neutrals are solidly grounded at main supply points. This 66-kv network plays the dual role of distribution system as well as transmission system, being tapped at will to supply power to lower-voltage distribution systems and large industrial plants.[1]

All but two of the 66-kv lines tying into Sunbury already existed in the general proximity and are simply being extended into Sunbury from other terminations. New 66-kv lines have been built, however, to Lock Haven and to Millersburg, tying in with existing lines to provide additional capacity required by increasing load. The 132-kv line between Sunbury and the large 220–66-kv substation at Siegfried forms a bulk-power channel between these two major supply points, terminating on the 66-kv bus at each end through a 50,000-kva 132/66-kv autotransformer. The 132-kv line initially is made up of a new section of 220-kv construction and an existing section of 132-kv construction. Later on, as required by the need for more capacity, the 220-kv construction will be completed all the way and the line then will be operated at that voltage.

Requirements of Transmission System

Basically, of course, the function of a transmission system is to transport power, for which it must have adequate capacity from the standpoint of conductor loading and voltage drop. In this case, the transmission is mainly to two regions: the main part of the system, lying eastward from Sunbury; and the northwestern portion, the load in which will be taken over largely by Sunbury. The one 66-kv line to the south will not only take over the load en route, but will bolster supply to the southern region.

All of the connections to Sunbury shown in Figure 2 have been governed either by the proximity of existing lines and the ease of tying them in, or by the need for additional transmission capacity to carry normal peak-load requirements in the regions to be served.

As to reliability, every reasonable effort is being made to provide lines that will stay out of trouble. New lines and extensions are of modern construction, resistant to lightning and sleet and located on private rights of way remote from highway and other such hazards. The older lines are being reinforced to improve their resistance to lightning and sleet.

The record of experience with lines of these types shows predomination though infrequent occurrence of inherently nonpersistent faults and a very rare occurrence on peak of persistent faults due to mechanical damage of some sort. The grouping of lines is such that momentary outage of any one line will not affect

---

Paper 49-153, recommended by the AIEE Relay Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer General Meeting, Swampscott, Mass., June 20–24, 1949. Manuscript submitted February 18, 1949; made available for printing May 23, 1949.

H. H. Green, J. A. G. Oewel, and O. Ramsaur are all with Pennsylvania Power and Light Company, Allentown, Pa.

appreciably any but those customers fed directly from the line itself. The cost of providing spare lines to avoid possible drastic measures for those extremely rare occasions when a long outage occurs on peak is not justified.

Functional Requirements of Relaying

Recognizing that no over-all line relaying can alleviate situations arising from persistent faults, the functional requirements of relaying for these lines are:

1. To clear all nonpersistent faults due to lightning and other transient causes quickly enough to avoid their becoming persistent because of arc damage at the point of fault. Experience has indicated that this can be accomplished with standard 8-cycle circuit breakers and fast protective relaying.

2. To reclose the terminal breakers quickly enough to give reasonable assurance that the faulted line will have been restored to service before another of its group is faulted. Experience with other 66-kv tie lines, including double-circuit lines, indicates that, in practically all cases where the faults were not simultaneous at the start, a reclosing time of two to three seconds is adequate. Even when outages are simultaneous, at least one line usually is restored successfully. An additional objective, of course, is quick restoration of service to loads tapped off the lines.

From the standpoint of channel reliability, it is recognized that persistent faults caused by mechanical damage are very infrequent and that they seldom result in simultaneous outage of two lines in a group, because their cause usually is localized. On the other hand, nonpersistent faults usually are caused by lightning, which occurs during a relatively few hours a year, so that outages of two lines are more apt to occur close together. It is for the latter type that relaying achieves its real aim.

The problem of stability does not enter into the need for fast relaying in this case, as the ties to the main network are stiff enough to give adequate synchronizing power under the assumed conditions.

Based on past experience on 66-kv tie lines with fairly fast protective relays and sequential reclosure of the 2 terminal circuit breakers within 3 seconds, it is reasonably certain that the transmission requirements enumerated will be satisfactorily met with the medium-speed protective and reclosing relaying about to be described, because:

1. There are comparatively few trip-outs of modern or modernized lines.

2. Most faults are transient in nature, so that reasonably fast clearing will keep the line ready for successful reclosure.

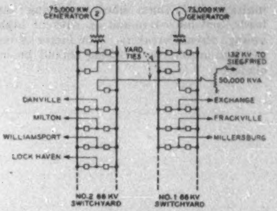

Figure 1. One-line diagram of initial installation at Sunbury

3. Since there are no double-circuit lines around Sunbury, there is little chance of simultaneous outages.

4. Even though two lines should go out together, it can be expected that at least one will be successfully restored within a short enough time to prevent serious results.

It is pointed out that fast tripping and reclosing of lines also gives improved service to tapped loads, which include some important customers and distribution supply substations.

Line Protective Relays

As might be surmised from what has been said about fast clearing of all faults, carrier-pilot relays are a practical requirement for all the lines leaving Sunbury. Only pilot relays can meet the requirements of simultaneous tripping of both terminal circuit breakers (or at least instantaneous sequential tripping, as may be encountered on two lines to be mentioned later), to minimize fault damage and to permit faster reclosure than would be possible with conventional relays. In fact, pilot relays are inherently fast enough to meet the requirements of fast clearing with circuit breakers of normal speed. This is especially important at the terminals away from Sunbury, where some of the circuit breakers are already in existence. The carrier pilot also provides a channel for emergency telephone communication.

Having decided upon carrier-pilot control of the relays as an essential requirement, there remained only the choice of basic relay types to suit the conditions imposed by the various lines. In this connection, the policy of tapping lines introduced some problems not found on untapped tie lines:

1. The difficulty of reaching faults at the ends of the taps, because of the increase in the apparent impedance seen by the relays at one terminal by current flowing over the tap from the other terminal. The permissible lengths of taps are limited by the fact that relay settings must be high enough, in terms of distance, to reach the tap ends with adequate margin, but, at the same time, must be low enough to permit carrying the maximum expected loads. Where the two limits of settings approach each other, there is also danger that a fault will produce enough current in one terminal to operate a carrier-starting element and send a blocking signal, but not enough current to operate the tripping element at the same terminal and stop the signal. This condition can be overcome by making the carrier-starting element directional, so that it will start carrier only for a fault in the nontripping direction at its terminal, thus establishing the condition that the tripping relays are free to trip the circuit breaker at the terminal where the fault on the tap is recognized, after which the other terminal will trip immediately. In no case encountered is it necessary to protect a tapped transformer, as fuses are used for this purpose.

2. The desirability of avoiding overtripping for faults on the low-voltage feeders from the tapped step-down substations. For very large transformers, a carrier terminal often is required for this, but for the lines covered by this paper, there are no tapped transformers large enough to require it for the type of relaying chosen. (Phase-comparison relays were rejected because certain transformers tapped to the lines were of sufficient capacity to require carrier blocking terminals with this type of relaying.) Consequently, no line has more than two carrier terminals. In this connection, it is pointed out that no attempt is made to avoid tripping the line for faults on the high-tension side of a tapped transformer, because it is expected that the transformer fuse will blow during the tripping time and thus disconnect the fault from the line and permit its immediate reclosure. These faults are so rare that special equipment to prevent line tripping is not warranted.

3. The necessity for opening low-voltage circuit breakers on transformers tapped off the lines, the low-voltage sides of which tie in to other transformers tapped off other lines. This back-feed into 66-kv line faults requires slowing up line reclosure long enough to open the ties, in addition to creating the problem of when and how to open the low-voltage circuit breakers. The problem is further aggravated by the fact that all of the tapped transformers have delta primaries, so that the only current flowing for a ground fault after the terminal circuit breakers trip is that caused by the unbalance in line-charging current.

For clearing phase-to-phase faults, review of the above and other conditions and restrictions imposed by the line connections and their maximum loads led to the conclusion that the relays best suited were the 3-element 3-zone impedance type *HZM*, with modified (offset) characteristics.[3] These relays offer a wide range of choice of settings and characteristics, and appear adaptable to any condition likely to arise. Also, the offset characteristic facilitates directional carrier starting.

As is customary for carrier-controlled

relays, all three elements will trip independently of carrier control, after their respective time settings. Zone *1* will be set to cover about 80 per cent of the line and will trip instantaneously through a directional element for faults in this range. Zone 2 will be set to cover the entire line and the taps, plus adequate margin, to trip through a directional element for faults in the far-end zone after a suitable co-ordinating time delay. Zone *3* will have its impedance characteristic almost completely offset, to make it largely directional and thus operative only for faults behind the bus and within a short distance out on the protected line; it will be set to outreach the second-zone element at the far end and will trip after a time delay longer than that of the second-zone element. It should be noted that the third-zone element will trip the circuit breaker at the terminal nearest a prolonged external fault, thus keeping the protected line in service to carry its tapped load.

For carrier-controlled tripping, the second-zone time element will be by-passed in the usual manner by the carrier auxiliary relay, to permit instantaneous tripping for faults within reach of the second-zone impedance and directional elements that are not blocked by a carrier signal. Operation of the third-zone element will start the carrier signal, and, being largely directional, it usually will start carrier only for faults requiring blocking, thus avoiding the condition of a blind terminal mentioned previously. Operation of the second-zone elements to trip will stop any carrier signal originating at the same terminal. While the third-zone element will also start carrier for faults within a short distance on the protected line, the second-zone element will definitely overreach it and stop carrier.

The scheme of operation outlined in preceding paragraphs assures instantaneous tripping of both terminal circuit breakers simultaneously for nearly all phase-to-phase faults anywhere on the protected lines. For those few cases where a fault on a tap will not operate the second-zone tripping relay at one end until the other end has tripped, at least instantaneous sequential clearing is assured.

Separate back-up relays for phase-to-phase faults are not being provided, because the relays on each phase operate as conventional 3-zone elements independently of the carrier pilot control, and because the phase relays will be taken out of service only one at a time for test. This is acceptable because full ground fault protection will be maintained at all times, because the phase relays remaining on the other two phases still offer limited back-up for the removed relay, and because relay testing is restricted to conditions of good weather, and so forth, when the probability of a pure phase-to-phase fault on the particular phase with limited protection is extremely low.

For phase-to-ground faults, the carrier-pilot protection is provided by two sets of zero-sequence directional and instantaneous overcurrent elements, one for tripping and one for starting the carrier blocking signal. As in the case of the phase relays, the starting combination operates only for the flow of zero-sequence current away from the line, so that the carrier blocking signal is transmitted only when required to prevent overtripping by the relays at the far terminal and is not transmitted for faults on the protected line.

The directional carrier-start feature is particularly valuable on the lines to Lock Haven and Williamsport, where there are no grounded-neutral transformers and where the main source of zero-sequence current is over the lines from Sunbury itself. For ground faults near Sunbury, there is practically no zero-sequence current in the Lock Haven and Williamsport terminals until after the Sunbury circuit breaker opens. This leads to the existence, at the Sunbury end of each of these lines, of a long zone in which a ground fault would operate a nondirectional starting element at the far end but would not operate the higher-set tripping element, thus blocking tripping by the carrier-controlled relays. With a directional starting element, this condition is avoided; instantaneous sequential tripping of the two terminal circuit breakers will result. While the back-up ground relay also should trip instantaneously for such a fault, it is desirable that the carrier-controlled elements stand on their own feet as far as possible.

Back-up protection for phase-to-ground faults is provided at Sunbury by simple inverse-time induction overcurrent relays with instantaneous attachments. At all terminals away from Sunbury, except at Siegfried, it was necessary to make these relays directional; one direction element was used to supervise both the inverse-time and instantaneous overcurrent elements.

The ground back-up relays are entirely independent of the carrier-controlled relays, so that either can be taken out of service for calibration and maintenance without losing full coverage for ground faults.

All directional relay elements are potential polarized, except the ground relays on the Siegfried line. Current polarization of the ground relays at Sunbury would have been unduly complicated by the double-bus arrangement, which would require special safeguards to insure that relays always would be polarized by a proper source of zero-sequence current. To insure correct potential for polarization of all relays and for other purposes, each line at Sunbury is being equipped

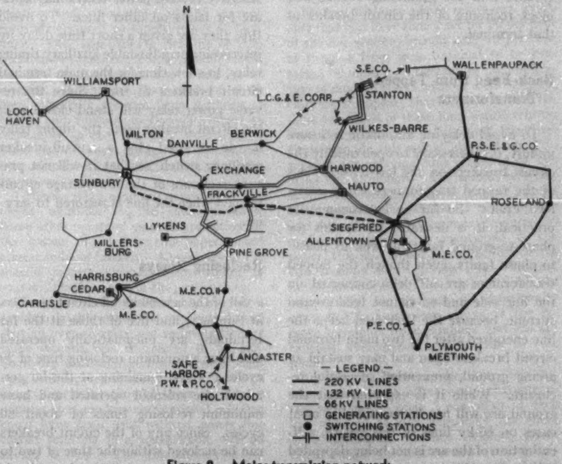

Figure 2. Major transmission network

with a complete set of three 66-kv potential transformers, connected Y-Y with neutral grounded, to supply all required potentials directly from the line itself. This cost little more than other methods, because it eliminates bus potential transformers. Each line does have a manually-operated switch for transferring the relays to another potential source whenever it is necessary to take the normal source out of service. In most cases, the relays on the terminals remote from Sunbury receive potential from bus potential transformers, as none of the adjacent stations except Siegfried has a double bus. The ground relays on the Siegfried line are current polarized. The current is supplied from a current transformer within the delta tertiary winding of the 132/66-kv autotransformer.

Since the 132-kv line to Siegfried is terminated by 66-kv circuit breakers only and a 132/66-kv autotransformer with solidly-grounded neutral at each end, the protective relaying is complicated a little by the necessity of providing complete protection of the terminal transformers. Because the protection offered by the line relays was not considered adequate under all conditions, differential protection for each transformer is provided in addition to the line relays. For this purpose, the transformers are equipped with bushing-type current transformers on the 132-kv side; a single-pole 132-kv grounding switch is provided at each terminal to force tripping of the far terminal. The transformer differential relays trip both the terminal circuit breaker and the grounding switch, and block reclosure of the circuit breaker at that terminal.

Back-Feed from Tapped Transformers

To avoid delaying automatic reclosure unduly, it is necessary to open quickly the circuit breakers on the low-tension sides of the tapped transformers where cross-feed exists. So far as is economically practical, it is desirable to do this for phase-to-ground faults as well as phase-to-phase faults, even though the tapped transformers are all delta-connected on the line side and so cannot feed ground current, because the back-feed keeps the line energized after the two main-terminal circuit breakers open and may sustain an arcing ground, preventing successful reclosure. While it is expected that the ground arc will not be sustained in most cases on 66-kv lines of this length, self-extinction of the arc is not being depended upon. For this reason, it is considered good practice to interrupt the back-feed, if it is possible to do so without resorting to expensive equipment for this purpose.

Remote tripping of the back-feed points over the carrier channels may have been practical but would have been expensive, so, after consideration of several other schemes, sensitive reverse-power relays were adopted.

Taking a tip from network relays, sensitive high-speed polyphase directional relays with watt characteristics are being used for this purpose. These relays are given a slight spring bias in the "reverse" direction, so that the contact will stand closed with full potential and zero current. Under normal conditions, there always will be enough load current toward the low-voltage bus to keep the relay open. With the line circuit breakers open, however, the presence of the spring bias, transformer core loss, and, in some cases, other load tapped off the line, will insure prompt closing of the relay as soon as the line circuit breakers open, if it has not closed already because of flow of positive- and negative-sequence currents into the fault.

The watt characteristic of the relay was selected because the wattless component of the reverse current may be either lagging because of transformer magnetizing current or tapped-load current, or leading because of line-charging current. The watt component is therefore the only one that can be depended upon for the proper direction.

For faults near Sunbury, some of these sensitive reverse power relays may operate for faults on other lines. To avoid this, they are given a short time delay by interposing an adjustable auxiliary timing relay, to allow time for the main-terminal circuit breakers to trip. Since the reverse power relay will stand closed with the circuit breaker open, the timing relay is de-energized by a circuit-breaker auxiliary switch, so that it will not prevent reclosure of the low-voltage circuit breaker when the line is restored to service.

Reclosing Relays

All of the new 66-kv oil circuit breakers at Sunbury, and five of those at the far terminals, are pneumatically operated and have a minimum reclosing time of 20 cycles. Those remaining at the far terminals are solenoid operated and have minimum reclosing times of about 60 cycles. Since any of the circuit breakers can be reclosed within the time of two to three seconds set as a limit, the policy is to reclose as quickly as possible with existing circuit breakers and under the particular conditions on each line. This means that reclosure will be fast enough if it is done as soon as it can be certain that the line is de-energized. On the other hand, reclosure is being speeded as much as possible without resorting to special equipment to do so. Therefore, the reclosing time of any circuit breaker is determined by the expected clearing time of the circuit breaker at the other terminal and on any low-voltage ties, plus time for arc deionization.

For reclosing the Sunbury circuit breakers, time is being allowed for sequential tripping of the far circuit breakers, because it is not certain that ground faults near Sunbury always will result in sufficient ground current at the far end to trip properly until after the Sunbury circuit breaker opens. In fact, as mentioned before, sequential tripping is almost a certainty for ground faults near Sunbury on the lines to Lock Haven and Williamsport. A time of only about 10 cycles is allowed for this, which is of little consequence.

Time is being allowed for tripping of the circuit breakers feeding back from low-voltage cross ties after the main-terminal circuit breakers trip, because of the time delay purposely introduced, as mentioned before, and because it is not certain that they will even start timing out before the terminal circuit breakers open. This adds some 35 cycles.

The result is that it is expected that both terminal circuit breakers will be reclosed within 30 cycles on the lines to Millersburg, Lock Haven, and Siegfried, which have no back-feed from low-voltage ties, and within about 65 cycles on all others except the line to Exchange, which will be about 100 cycles because it has two back-feeds that may trip sequentially with respect to each other as well as to the 66-kv circuit breakers.

The reclosing time is varied by setting up the reclosing circuit as for one-shot instantaneous reclosure, but delaying it with an auxiliary relay with adjustable time delay.

Because each line is terminated on two circuit breakers at Sunbury, a selector switch is provided to select the circuit breaker that will be reclosed automatically. If reclosure is successful, the other circuit breaker will be reclosed manually. If the one automatic reclosure is not successful, any further tests also will be manual.

Automatic reclosure of any circuit breaker is blocked by the manual switch that removes carrier control of tripping

It is also blocked by operation of bus differential relays or by manual tripping of the circuit breaker by the control switch. Manual reclosing restores the automatic reclosing feature.

On the low-voltage ties, circuit breaker reclosure will take place after a time delay following restoration of the 66-kv line to service. As on a secondary network, proper conditions for reclosure are indicated by a directional relay so connected that it acts as a phasing relay.

Bus Protection

While bus protection does not come under the heading of line relaying, a brief description of the Sunbury bus protection may be of interest.

Linear couplers were selected for differential protection of each of the four 66-kv bus sections because of their superiority over other conventional methods considered.[3] This method eliminates any possibility of bushing current transformer saturation by the heavy currents to be expected for nearby line faults, and, at the same time, retains the simplicity of a straight differential scheme. Simplicity is highly valued.

The linear couplers are connected by multiconductor control cable, without benefit of shielding, because calculations of induced voltages in the relay circuits for ground faults in the vicinity of the switchyard were reassuring, even when based on pessimistic assumptions such as no spiraling. Actually the cable is spiralled about every 15 inches, so that induced voltage between conductors should be practically zero. Voltages induced along the conductors are equal in all conductors and hence produce no relay current.

Considerable thought was given to the selection of a satisfactory method of supervising or checking the linear coupler circuits. The method adopted was suggested by the manufacturer. Absence of short circuits is checked by switching high-resistance low-reading voltmeters in parallel with the relays to test for abnormal differential voltages, such as would be caused by short-circuited linear couplers. Continuity of the circuits is checked by introducing about 0.5 volt from an external source. This is done, without opening the circuits, by applying the voltage across a resistor of low ohmic value which is left permanently in the circuit. Correct readings of the voltmeters, which are in parallel with the relays, indicate continuous circuits.

The yard tie circuits are protected by percentage differential relays. Since both yard tie circuits are tapped, 3-way differential circuits are employed. The 66–132-kv autotransformer in the Siegfried line at Sunbury is included in the yard-tie differential relay zone of protection. The operation of the differential relays trips the two 66-kv circuit breakers and closes a single-phase 132-kv grounding switch which insures tripping the Siegfried terminal. A similar arrangement is provided for the transformer protection at Siegfried substation. The line relays receive current from the 66-kv current transformers and thus provide limited back-up protection for transformer failures.

Discussion

C. E. Asbury (The Commonwealth and Southern Corporation, Jackson, Mich.): This paper describes some interesting relay applications and is perhaps typical of some modern trends in system planning such as tapping high-voltage transmission lines to serve load without the use of high-voltage circuit breakers. This particular plant is perhaps unusual in one respect, in that it has eight major ties into the transmission system. Often in the initial installation of one or two units at a new plant site, only two or three transmission lines connect between the plant and system, and often these are quite long electrically. Such conditions, of course, are brought about because of the availability of plant sites and their location relative to the existing transmission system and load centers.

It is noted that the switching arrangement used at Sunbury consists of two sets of double 66-kv busses, one for each generator. It would be interesting if the authors would point out the advantages of the two sets of double busses with two yard tie circuit breakers between them, over that of one double bus often used for installations similar to this. It also would be interesting to know how future generators will connect to these busses.

This switching arrangement includes two circuit breakers for each line connection, and it is not clear in the paper whether these are normally operated both closed or with one normally open. It would be interesting to know the method of operation and the location and connections of the current transformers used to supply relays at Sunbury. The approximate length of the transmission lines connecting Sunbury with the rest of the system also would be of interest. It appears that some of these lines, especially the two from Sunbury to Milton and Sunbury to Danville, might be reasonably short. We were wondering if these lines are short enough for the application of pilot-wire relays, and if pilot-wire relays were considered.

Different relay engineers would have different solutions to the same problem. Some other points of view on protection for the system outlined in this paper would appear to be of interest. Knowledge of the specific system characteristics would, of course, influence some of the applications.

The paper states that stability was not a problem in this particular application, and that an over-all relay and reclosing time of three seconds was considered to be adequate for transmission lines between Sunbury and the rest of the system. Based on a total reclosing time of three seconds, it appears that modern conventional relaying could have been used without power line carrier resulting in a considerable over-all saving in cost. The communication requirements mentioned could be satisfied with a much more economical power-line carrier of the Simplex multistation type. Such a communication channel probably would not require the use of line traps at a number of points where they were required for relaying.

Modern distance phase relays are available that can have zone *1* set for 90 per cent of the line section, leaving only 10 per cent of the line from each terminal to be protected by zone *2*. Considering the application of modern relays without a carrier pilot channel, it appears that at least one of the main terminals of these lines would trip by zone *1* step distance relays, and, based on three seconds this would leave about $2^{8}/_{10}$ seconds for relaying and reclosing of the other two terminals. The second terminal should trip sequentially on zone *2*, which could probably be set for 15 or 20 cycles, and even if the third terminal required 35 cycles for tripping as mentioned in the paper, this still would leave approximately two seconds for reclosing time. Ground faults probably could be cleared similarly sequentially, by the use of directionally controlled instantaneous relays at the remote terminals from Sunbury and instantaneous overcurrent attachments at the plant.

In this particular application, step distance relays with offset circle characteristics were used. Zone *3* was offset at each line terminal to give essentially the effect of a directional distance element, directional out of the line section at each terminal. It must, of course, be realized that where this arrangement is used about the only function of zone *3* is for carrier starting and that zone *3* provides little back-up protection. One reason for being limited as back-up protection is the interposed feed of short-circuit current from other transmission lines terminating on the same bus. This infeed at each line terminal limits considerably the reach of zone *3* as a back-up element. This would be especially true for all lines terminating at Sunbury Plant. Such limitation is not placed on zone *3* when it is set to provide back-up protection of its associated line section. Another reason for the limitation of zone *3* as back-up protection, where this method is applied in a system equipped with other distance relays applied in the conventional manner, is that zone *3* of all lines which are set for back-up protection on its particular line section and, therefore, any additional back-up protection such as provided from adjacent carrier having zone *3* set looking out of its line section, is of little benefit. Such an arrangement would provide double back-up protection for some lines and will probably result in zone *3* having the same time delay setting for two or more zone *3* settings at the same substation. If this arrangement is used and a fault occurs in a line section requiring the operation of zone *3* back-up relays, then two lines will be opened at the same substation instead of one. It would be interesting if the authors would point out how zone *3* time delay was co-ordinated with zone *3* of adjacent line sections which may have been equipped with conventional distance relays.

Apparently, the zone *3* elements were offset to look out of the line section at each terminal to avoid starting carrier due to load currents, assuming zone *3* elements had been set to cover the line section, including tapped spurs to loads. It is apparent that with the settings as described in the paper, it is not necessary to start carrier by zone *3* before tripping the line by zone *2*, since zone *3* covers only a small portion of the protected section. With this type of operation, a standard impedance element could have been used at each line terminal to start carrier as long as it was set to reach farther out of the line section than zone *2* at the opposite end of the line. Since it is only necessary to cover the line plus a small margin by zone *2*, such an impedance starting element could have a short setting and can be less susceptible to pick-up on load than zone *2* at the opposite end of the line. This arrangement would permit the use of zone *3* as back-up protection for its own line section.

The paper describes the use of ground relays where one directional element was used to supervise both the inverse and the instantaneous over-current element. It would be interesting to know what type of relays were used for this arrangement and whether or not the instantaneous elements were directionally controlled.

Mention is made of T-tap loads on a number of 66-kv lines which have back-feed from other low-voltage lines. Apparently the other low-voltage sources of these loads are sufficient to carry the loads with the 66-kv line out of service, since high-speed tripping and reclosing is not utilized. It appears that if the load had been such that the emergency supplies were inadequate with the 66-kv line open, which probably will be true in the future as the load increases, it may be desirable to add additional terminals of carrier to provide high-speed tripping and reclosing of these terminals. Application of reverse power relays biased with spring tension to trip on full voltage with no incoming power is an interesting application. Apparently, the system loading and supply is such that there is no back-feed at any of these terminals from low-voltage ties during light-load conditions.

O. Ramsaur: Mr. Asbury asks a number of questions that are quite pertinent to the subject and have probably arisen in the minds of other readers of the paper.

The two sets of 66-kv busses were adopted for physical reasons. This arrangement provides the greatest number of future bays in the available space, greatly facilitates connections to the generators and get-away of the east and west lines without having circuits crossing each other, and minimizes the distance from the switchyard to the control house, which is located between the two sets of busses. It should be noted that the amount of switchyard equipment is practically the same as for one long double bus, because the yard ties serve dual purposes (at present they are used for the 66/132-kv transformer and a 66/4-kv stand-by auxiliary supply transformer; in the future they will be used to terminate two 220/66-kv transformer banks).

The double-bus arrangement, together with the automatic sectionalizing afforded by the yard ties, is required for reliability and for flexibility of operation. Initially all circuit breakers shown in Figure 1 of the paper will be operated closed. As the station grows in capacity, however, it will be necessary to "split" the 66-kv bus to limit short-circuit currents. The double-bus arrangement facilitates a flexible mixture of east and west lines on each of two independent busses, by opening the proper circuit breakers, with provision for transferring to the other bus for outage of any bus section.

Future generation will be connected to a 220-kv bus, which will be tied to the 66-kv busses through transformers, as mentioned before. The current transformers for the line and yard-tie relays at Sunbury are bushing type, located in the bus sides of the circuit breakers. The two sets associated with each circuit are paralleled. The linear couplers for bus protection are located in the line sides of the circuit breakers.

The line lengths vary from 15 miles for the line to Milton to 75 miles for the 132-kv line to Siegfried. Pilot-wire relays were considered for the Milton line; but the carrier-current pilot was selected for its greater reliability, there being no great difference in over-all cost.

Speed of fault clearing is usually dictated by the lesser of two times: (1) that required to avoid instability and (2) that required to avoid line damage. It was the intention of the authors to bring out in the paper that, since there is no problem of instability, the aim of fast fault clearing is to prevent line damage. Also, since the allowable outage time of two or three seconds is comparatively long, there is plenty of time left for reclosure, even after waiting to disconnect the line from sources of feedback.

Considering co-ordination with existing relays on adjacent circuits, neither conventional nor impedance relaying would have been fast enough for safety from line damage, especially for faults in the end zones away from Sunbury. Instantaneous ground relays would not operate sequentially, because there is practically no increase in current at Sunbury after the far-end circuit breaker opens. Carrier-current relaying was required, therefore, to avoid line damage; and emergency communication was mentioned only as a by-product, although it is considered quite valuable.

It is true that the reversed zone *3* elements offer only partial back-up protection for faults on either the protected line or other lines, because of the interposed currents mentioned. For back-up coverage of the protected line, it is believed that little would be gained by using zone *3* in the conventional manner, however, because failure of the zone *1* and zone *2* elements to trip is almost always due to failure of something common to all three elements—open trip coils, open current circuits, loss of polarizing potential, loss of tripping potential, stuck timers, faulty auxiliary switches, and so forth. Rarely can failure to trip be attributed to something associated only with a particular relay element. Also, it is seldom that a fault does not involve ground current; so that the ground relays usually back up the phase relays anyhow. There is little chance that a pure phase-to-phase fault will occur at the same time that failure to trip is due to something peculiar to one relay element. And back-up coverage of adjacent lines by the reversed zone *3* is greater for the same setting than a conventional zone *3*. This is important where coverage is limited by ability to carry load.

Since the coverage of the reversed zone *3* elements is less than that of the instantaneous relays on adjacent line sections employing conventional relays, there is no problem of co-ordination. Nor would there be any if zone *3* were used in the conventional manner, for the same reason. Where adjacent lines have distance relays, it is assumed that if an adjacent zone *2* does not trip, then zone *3* also will not, for the reasons mentioned; and again there is no need for co-ordination. The use of a standard impedance relay to start carrier in the manner described by Mr. Asbury should be satisfactory, although it would add three impedance elements at each terminal.

Directional supervision of both instantaneous and inverse-time ground relays is accomplished with two standard relays. One is a combination of a high-speed directional element and a directionally controlled inverse-time element in one case. The other is an instantaneous plunger-type relay, which trips through the directional element in the first relay, an extra stud having been provided for this purpose. The instantaneous element is not directionally controlled. Each of the low-voltage sources of loads with backfeed is able to carry the load alone, the backfeed resulting from 2-way supply to these important loads. As the loads increase, additional transformer capacity will be provided; but this capacity is not expected to be large enough to require carrier-current terminals. No backfeed under light-load conditions is expected. Should it occur unexpectedly, the reclosing relay set-up inherently provides for holding the circuit breaker open until voltage of the proper magnitude and phase angle to carry load is again established; and, if the other source fails, the load will be transferred.

A Thermal Converter for Telemetering and Totalizing

WILLIAM C. DOWNING, JR.
MEMBER AIEE

JUST 20 years ago, Professor Paul M. Lincoln described a "thermal converter" for use in the telemetering and totalizing of large power loads.[1] At that time the installations employing this instrument were less than a dozen in number. Today the thermal converter is generally accepted as an important primary element in the measurement and control of a large portion of the power systems of this country. A number of these installations have been described in *Electrical Engineering* and elsewhere.[2-8]

The thermal converter may be described briefly as an instrument which generates a direct electromotive force accurately proportional to the power flowing in the a-c circuit which it is connected to measure. The voltage so generated may be transmitted readily over considerable distances and recorded or indicated on a potentiometer for telemetering; the output circuits of two or more converters may be connected in series to totalize the power from a number of sources. Since only the series addition of direct voltages is involved, the circuits totalized may differ in types or frequencies, and loads may be subtracted, as well as added, in attaining a record of total load.

In principle, the thermal converter comprises an electric circuit in which the difference of the power generated in two heaters is proportional to the power measured. The temperature difference so produced is measured by thermocouples, the voltage from which is thus a measure of power. In addition to the measurement of power, the thermal converter may be adapted to the measurement of reactive power, power factor, current, or voltage.

Types of Thermal Converters

The two types of converters commercially available may be classified according to the means by which heat is transferred from the heaters to the thermocouple junctions. In the "indirectly-heated" type,[1] the a-c heater circuit is insulated electrically from the thermocouple circuit but is in close thermal contact with it. In the "directly-heated" type,[9] a common circuit is provided for heaters and thermocouples, separation of the a-c and d-c components being obtained by a bridge circuit which, properly balanced, eliminates the alternating voltage from the output circuit.

In the indirectly-heated type, the interposing of electrical insulation inevitably results in some temperature drop between heater and thermocouple junction and in a delay in the response of the thermocouple temperature to a rapidly changing load. Nevertheless, the time of response of the commercial thermal converter of this type, defined, in the usual manner for thermal meters, as the time required for the output to reach 90 per cent of its ultimate value, is approximately 4 seconds. In the directly-heated type of thermal converter, on the other hand, where the heat is generated directly in the thermocouple circuit, the speed of response depends chiefly upon the dimensions and material of the wires composing the thermocouples; a response time of less than 1/2 second readily is obtainable.

In the majority of installations it may be questioned whether the faster speed of response is of more than academic interest, since, where load changes occur only as small increments of the total load, the difference in the record obtained may be barely discernible, but, in control applications, the faster response does have marked advantages. This means, in general, that a high-speed electronically-balanced potentiometer recorder is required to take full advantage of the faster response of the directly-heated-type thermal converter.

Against the disadvantage of the indirectly-heated type of converter in response speed, there may be considered its advantage of complete freedom from a-c component in its d-c output circuit, due to the electrical insulation between circuits. In the directly-heated type described, however, alternating voltages exist simultaneously with the direct voltages in the thermocouple circuit, and precise balancing must be attained to reduce the alternating voltage component to a value which can be tolerated by the receiving equipment. While the functioning of a mechanically-balanced potentiometer is not adversely affected by a considerable a-c component, the electronically-balanced potentiometer, in which the advantage of faster converter response is best realized, may be rendered sluggish in its action by an alternating voltage component of only a few per cent of the magnitude of the direct voltage output.

In order to combine the advantages of efficiency and speed of response of the directly-heated type of converter with the freedom from a-c component of the indirectly-heated type, and at the same time to provide facility of adjustment and manufacturing control of characteristics, a new thermal converter recently has been developed.

In this converter each thermocouple junction is in direct contact with its associated heater, but each heater circuit is isolated by means of multiple-winding potential and current transformers; since but one point of contact exists between the thermocouple circuit and each of these isolated heater circuits, the development of an alternating voltage in

WILLIAM C. DOWNING, JR. is with the Sangamo Electric Company, Springfield, Ill.

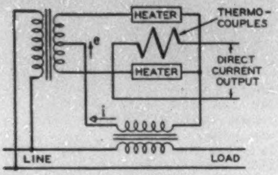

Figure 1. Basic thermal converter circuit

the output circuit is effectively eliminated.

Basic Circuit of New Converter

The basic circuit of any thermal wattmeter is illustrated, for the case of an indirectly-heated converter, in one of its simpler forms in Figure 1 (for simplicity only two thermocouples are shown). Two heaters of equal resistance, R, are supplied in series from the low-voltage secondary of a potential transformer whose primary is excited from the line, so that, due to voltage, e, alone, a current, $e/2R$, circulates through the heaters. A current transformer, excited by line current, is connected through a center tap in the potential-transformer secondary to supply the heaters in parallel so that, due to current, i, alone, current $i/2$ passes through each heater. In one heater these currents are additive and, in the other, subtractive; one heater, accordingly, develops heat at a rate proportional to $(e/2R+i/2)^2R$ and the other heater, $(e/2R-i/2)^2R$. The difference in the power developed in the two heaters is ei, or is proportional to the instantaneous power of the circuit measured; the temperature difference, measured by the thermocouples associated with these heaters, is thus a measure of the average power.

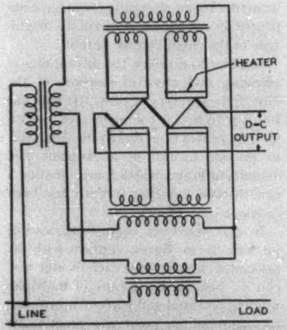

Figure 2. Basic thermal converter circuit with isolating transformers to permit direct contact between heaters and thermocouples

In the foregoing example it is obviously impossible to connect the thermocouple circuit directly to the heater circuit at more than one point. If, however, each heater is replaced by an isolating transformer with as many separate secondaries and heaters as there are thermocouples, an equivalent circuit is obtained, as shown in Figure 2, in which each thermocouple junction may be in direct contact with its associated heater.

In the new thermal converter, the two extra transformers introduced in Figure 2 are eliminated by the use of multiple-winding potential and current transformers, as shown in Figure 3. For each thermocouple junction there is an associated heater and a completely isolated secondary winding on both the potential transformer and the current transformer. Each heater circuit consists of a heater in series with a potential-transformer secondary coil and a current-transformer secondary coil; in half of the heater circuits, the polarity of the connection between the potential- and current-transformer secondary windings is such that the effects of line voltage and line current are additive, while in the other half the polarity is reversed to provide a subtractive effect. The general condition, then, that one set of heaters is heated proportionally to $(e/R+i)^2$ and the other to $(e/R-i)^2$ is met as before.

It will be noted that the series interconnection of potential- and current-transformer secondary coils of Figure 3 introduces no adverse inductive effects, such as might produce appreciable phase-angle errors in the resultant measurement, since the current transformer represents a noninductive burden to the potential-transformer output, and, conversely, the potential transformer appears noninductive to the current-transformer output. For example, if potential only is applied to the converter, all circuit constants being equal, the magnetomotive force resulting in the current transformer due to the circulating current flowing through the coils of additive connection will be exactly balanced by the circulating current flowing in the opposite direction through the subtractively-connected coils.

The single thermocouple, with each of its junctions in contact with a heater, also may be replaced, without affecting the principle of measurement, by two opposing thermocouples, each measuring the temperature difference between a heater and some common reference point. The use of opposing thermocouples in pairs, instead of the single thermocouple, offers structural advantages and reduces the thermocouple junction temperatures without affecting the temperature difference between junctions.

Thermocouple Construction and Characteristics

The construction of the basic thermocouple-heater unit is illustrated in Figure 4. The thermocouple consists of #38 molybdenum wire butt-welded to #33 constantan wire. The heater, of #33 constantan wire also, is welded at right angles to the thermocouple wire on the constantan component close to the thermocouple junction. The cross thus formed is in turn welded to four terminals, so located that the distance from junction to terminal is 0.125 inch for the constantan wires and 0.225 inch for the molybdenum wire. The terminals are in intimate thermal contact with, but electrically insulated from, the plate in which they are mounted; the plate, in turn, being of high thermal conductivity, insures that all terminals are maintained at substantially the same temperature and functions as a "heat sink."

To avoid conductive pickup of alternating voltage from the heater circuit by the thermocouple, the ideal junction between heater and thermocouple should be a point contact. Such a contact obviously would be undesirable from the point of heat transfer, as well as unattainable, but it follows that the cross weld between heater and thermocouple, and the butt weld between the components of the thermocouple, must be symmetrical to prevent any component of alternating voltage along the path of the d-c circuit, By careful control of these welds, it has been found entirely practical to keep this a-c component well within the allowable limits.

When current is passed through the heater, the temperature rises until the

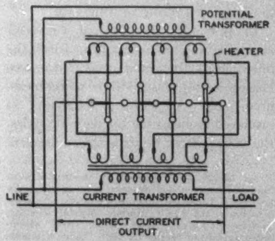

Figure 3. Basic circuit of new thermal converter

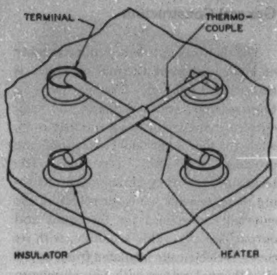

Figure 4. Heater-thermocouple unit

heat loss by conduction and by convection (radiation being negligible) balances the heat input. The "cold junctions" of the thermocouple at the terminals are held, by their close thermal association with the heat sink, at the reference temperature, while the "hot junction" approaches the maximum temperature of the heater.

The rate at which the temperature of the thermocouple junction rises—and, therefore, the speed of response of the converter—depends in general upon the ratio of heat storage capacity of the system to the rate of heat loss from it. If only the heat loss by conduction, which constitutes the major portion of the total heat loss, is considered, it will be seen that for any given materials the lengths of the heater and thermocouple wires become the most important factor in speed of response, since both the heat storage capacity and the conductive heat loss vary directly with the cross section of the wire. Faster response means shorter lengths; this in turn involves either a smaller cross section or higher conductive losses. Practical design, then, indicates a compromise between losses and speed of response such that the response is limited to that which is necessary to, and which can be utilized by, the equipment operating from the thermal converter. With the thermocouple unit described above, the output voltage follows closely an exponential curve, reaching 90 per cent of its ultimate deflection in approximately one second; with this response speed, the potential loss at rated voltage is limited to 2.4 watts and the current circuit loss at rated current to 0.9 watt per element.

Since the accuracy of the thermal converter requires that the output voltage must vary proportionally with the load measured, the electromotive force developed in any thermocouple pair must be proportional to the difference of power input to the heaters associated with that pair. It also may be shown that, if this proportionality is to be maintained for all conditions of voltage, power factor, and load (including reversal of load), each individual couple must generate a voltage proportional to the power developed in its associated heater.

The proportionality of power input to voltage generated in a thermocouple-heater unit depends upon the relation between the power input and the temperature difference between thermocouple junctions, and upon the relation between this temperature difference and the thermocouple voltage. If either of these relations varies from strict proportionality, the other relation must vary in the same degree, but in the opposite manner, if the output voltage is to vary directly with the power input.

In a constantan-molybdenum thermocouple the electromotive force increases more rapidly than the temperature difference. This factor is compensated, however, by the tendency for the temperature difference to increase less rapidly than the heat input. This latter factor is the combination of several effects: the heat loss by conduction through the constantan and the heat loss by convection both increase more rapidly than the temperature difference, whereas the heat loss by conduction through the molybdenum rises less rapidly than the temperature difference.

The temperature coefficient of thermal conductivity of molybdenum, as for most pure metals, is negative (that is, the conductivity decreases with rising temperature), but the coefficient is positive for constantan, as is characteristic of alloys in general. This difference provides a means for controlling the over-all relation between heat loss and temperature difference, by so varying the dimensions of the two materials as to change the proportion of heat flow through them. With the present dimensions, for example, the conductive heat loss through the molybdenum is roughly 1/2 that through the constantan, and the resultant load curve of the thermal converter is linear within ±1/4 per cent. If the diameter of the molybdenum thermocouple wire were increased and the diameter of the constantan wire decreased, the net heat loss might be left unchanged, but the proportion of heat flow through the two materials would be altered; in such an example, then, the increase in proportion of heat flow through the molybdenum would cause the converter output voltage to rise more rapidly than the measured load.

Adjustments

A schematic diagram of a complete, single-element, thermal converter is shown in Figure 5. Each such unit is complete in itself, and as many identical units are employed as are necessary for the type of circuit to be metered. For the measurement of 3-phase, 3-wire circuits for example, two single-element units are provided in a single enclosure.

Where a number of thermal converters are connected in series for totalizing, if the instrument transformer ratios of the various circuits to be totalized differ, the maximum output ratio is specified for the circuit having the highest instrument-transformer ratio. The output ratios of all other converters are reduced propor-

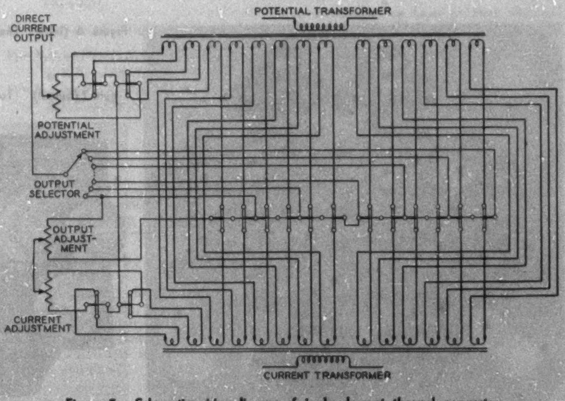

Figure 5. Schematic wiring diagram of single-element thermal converter

tionally to the ratios of the instrument transformers with which they are used, so that the millivolt output per kilowatt of primary power will be the same for each converter. Means should be provided, therefore, for the continuous adjustment of the output ratio from zero to the maximum output of the instrument.

Each converter element includes, for the measurement of power, six thermocouple pairs permanently connected in series. The external circuit is connected into this string of thermocouple pairs through a selector switch, in such manner that any number of thermocouple pairs, from six to one, may be included in the output circuit. A small voltage divider, permanently connected across the final thermocouple pair, provides for fine adjustment of the output ratio over a range of 1/6 of the maximum output ratio; this, in conjunction with the selector switch, permits continuous adjustment of the output ratio to any value up to the maximum rating of 60 millivolts per kilowatt for a 120-volt 5-ampere converter.

In addition, means must be provided for balancing out any errors which may exist due to dissymmetry of the input or output circuits. It may be shown (see the Appendix) that differences of heater resistances, or of the "efficiency" with which heat is translated into voltage in various thermocouples, result in an equation of the form

$$\text{Output voltage} = \Delta V = KEI \cos\theta + K_eE^2 + K_iI^2 \qquad (1)$$

The E^2 and I^2 terms, while small compared to the power term $EI \cos\theta$, nevertheless represent errors for which correction must be made if accuracy is to be attained. At no load, but rated voltage, for example, an appreciable E^2 term would cause an incorrect zero indication on the potentiometer.

The corresponding condition, of current but no voltage on the converter, would of itself be of no practical significance; however, when superimposed upon the main term, $EI \cos\theta$, of the expression for electromotive force, an appreciable I^2 term would result in load-curve distortion, power-factor errors, and inequality of output ratio on forward and reverse power flow.

These errors may be corrected readily by the inclusion, in series with the output circuit, of adjustable sources of direct voltage, proportional, respectively, to E^2 and I^2, which may be set to be exactly equal and opposite to the error terms. Two thermocouples, with heaters supplied from the potential transformer, are additively connected in series, across a small adjustable resistor connected as a voltage divider; by varying the position of the resistor brush, the voltage between it and the connection between the two thermocouples may be caused to vary in either direction from zero. A similar voltage divider and pair of thermocouples, heated by the current transformer only, provides a voltage proportional to I^2 which can be adjusted in either direction. In adjusting the thermal converter, then, the E^2 voltage divider is adjusted until, with rated voltage but no load, the output of the converter is zero, and the I^2 voltage divider is adjusted until the output at some load is the same in magnitude as, but of opposite polarity to, the voltage obtained when the same load is applied in the opposite direction.

General Construction

The thermocouple and heater assembly of a single-element thermal converter is shown in Figure 6. The six pairs of thermocouples which comprise the main output circuit are in the two center rows, while the four additional couple units are provided for E^2 and I^2 correction. The terminals, extending through the mounting plate, provide studs for soldering the external connections for the input and output circuits. This assembly, with its cover, is electrically insulated from, but in close thermal contact with, four aluminum studs which support it in the base. By providing this additional insulation between the output circuits and ground, the level of the insulation between the thermocouple terminals and their mounting plate may be reduced to that necessary to insulate between parts of the thermocouple and heater circuit.

The potential transformer is of conventional shell-type design, with 12 2-turn secondary coils for supplying heaters of the power group of couples and two 1-turn secondary coils for supplying the E^2 thermocouple heaters. The current transformer is of the core type and is made of a high permeability alloy in order to provide adequate ratio and phase-angle characteristics. In order to take full advantage of the high permeability of the core material, solid laminations (without gaps) are employed, and the primary and secondary coils are wound on the assembled core. Twelve 8-turn secondary coils provide for supplying heaters of the power group of thermocouples; two 6-turn secondary coils, for the I^2 heaters. The primary coil is wound on

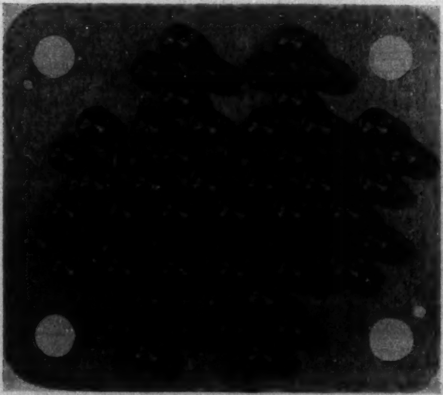

Figure 6 (left). Thermocouple assembly of single-element thermal converter

Figure 7 (below). Two-element thermal converter, with cover removed

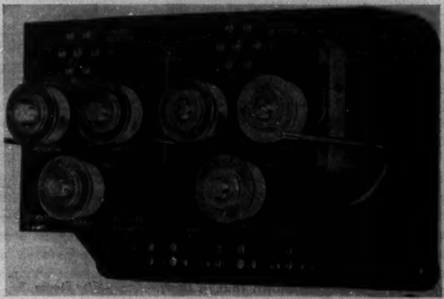

Figure 8. Two-element thermal converter

one end section. The secondary windings are disposed along each leg of the rectangular core. The interconnections between potential-transformer and current-transformer secondary coils are arranged so that the magnetizing effect of current due to potential cancels in adjacent coils of the current transformer. The combined phase angle of both transformers thus may be kept within ±15 minutes throughout the operating range of the instrument, a feature which is of importance in the case of a tie-line application where the power transferred may be largely or wholly reactive.

The voltage dividers for adjustment of potential balance, current balance, and output ratio, consist of six turns of manganin wire supported by a spirally-grooved steatite spool; an adjustment knob, operating on a thread of the same pitch as that of the spool, carries the brush which makes contact, under heavy pressure, with the manganin wire. A knurled locking nut is provided to secure the adjustment. These three resistors, together with a link and studs for selection of the output range, are mounted on a panel in the front of the converter element.

A dust-tight case and cover, with molded-melamine terminal-block construction, encloses the thermal converter. A 2-element converter, complete except for cover, is illustrated in Figure 7, and, with cover in place, in Figure 8.

Conclusion

In output ratio, speed of response, and freedom from a-c component, this new converter represents a compromise between the characteristics of existing converter types, which, it is felt, is distinctly practical in its application to present-day receiving instruments. Early tests indicate that its accuracy under all conditions of load, voltage, or temperature equals or exceeds that of existing converters. Its characteristics are controllable in manufacture and its adjustment facilities permit full advantage to be taken of its inherent accuracy. The design is, in general, adaptable to the measurement of any type of circuit of commercial voltage, current, and frequency rating.

Appendix. Derivation and Illustration of Equation 1

In Figure 9:

e, E = line voltage
i, I = line current
i_1, i_2 = heater currents
R_1, R_2 = heater resistances
p_1, p_2 = instantaneous heater power
P_1, P_2 = average heater power
θ = phase angle between E and I
V_1, V_2 = output voltages
N_1, N_2 = "efficiency" of conversion from power to thermocouple voltage
ΔV = net output voltage
K, K_e, K_i = constants

By Kirchhoff's laws

$$e = i_1R_1 - i_2R_2$$
$$i = i_1 + i_2$$

From which the heater currents are

$$i_1 = (iR_2 + e)/(R_1 + R_2)$$
$$i_2 = (iR_1 - e)/(R_1 + R_2)$$

The instantaneous heater inputs are

$$p_1 = i_1^2R_1 = (iR_2 + e)^2R_1/(R_1 + R_2)^2$$
$$p_2 = i_2^2R_2 = (iR_1 - e)^2R_2/(R_1 + R_2)^2$$

The average heater inputs are

$$P_1 = [(I^2R_2^2R_1) + 2EI\cos\theta \times R_2R_1 + E^2R_1)]/(R_1 + R_2)^2$$
$$P_2 = [(I^2R_2R_1^2) - 2EI\cos\theta \times R_2R_1 + E^2R_2)]/(R_1 + R_2)^2$$

The thermocouple outputs are

$$V_1 = N_1P_1 = (I^2R_2^2R_1N_1 + 2EI\cos\theta \times R_2R_1N_1 + E^2R_1N_1)/(R_1 + R_2)^2$$
$$V_2 = N_2P_2 = (I^2R_2R_1^2N_2 - 2EI\cos\theta \times R_2R_1N_2 + E^2R_2N_2)/(R_1 + R_2)^2$$

The net output is

$$\Delta V = V_1 - V_2$$
$$= I^2 \times \frac{R_1R_2(R_2N_1 - R_1N_2)}{(R_1 + R_2)^2} + EI\cos\theta \times \frac{2R_2R_1(N_1 + N_2)}{(R_1 + R_2)^2} + E^2 \times \frac{(R_1N_1 - R_2N_2)}{(R_1 + R_2)^2}$$
$$= I^2K_i + EI\cos\theta \times K + E^2 \times K_e \qquad (1)$$

To illustrate the effect of the I^2 term in load-curve distortion, power-factor errors, and difference of output ratio on forward and reverse power flow, let $K = 0.1$ millivolt per watt, $K_i = 0.04$ millivolt per ampere squared, and $K_e = 0$.

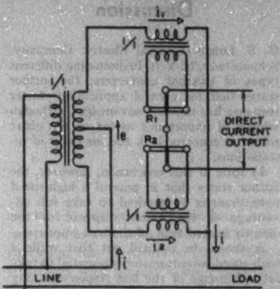

Figure 9. Basic thermal converter circuit for illustrating effect of unequal resistance and conversion efficiency

Case I. $E = 100$ volts, $I = 10$ amperes, $\cos\theta = 1.0$

$\Delta V = 100 + 4 = 104$ millivolts

Case II. $E = 100$ volts, $I = 5$ amperes, $\cos\theta = 1.0$

$\Delta V = 50 + 1 = 51$ millivolts

(ΔV should be 52 millivolts.)

Case III. $E = 100$ volts, $I = 10$ amperes, $\cos\theta = 0.5$

$\Delta V = 50 + 4 = 54$ millivolts

(ΔV should be 52 millivolts.)

Case IV. $E = 100$ volts, $I = -10$ amperes, $\cos\theta = 1.0$

$\Delta V = -100 + 4 = -90$ millivolts

(ΔV should be -104 millivolts.)

Discussion

G. S. Lunge (General Electric Company, Schenectady, N. Y.): In discussing different types of thermal converters, the author states that for control applications faster response has marked advantages, although seldom of importance as far as the chart record is concerned, in the majority of installations.

In spite of this conclusion, however, the author states that in general a high-speed potentiometer is required to take full advantage of the faster response of the directly heated type of thermal converter.

It should be pointed out that while a high-speed potentiometer is essential to take full advantage of the fast response of any high-speed thermal converter, this potentiometer need not necessarily include recording features.

High-speed response in a recorder for rapidly varying measured quantities will simply result in producing a wide band of ink and hence a less legible chart record if ordinary chart speeds such as 1, 2 or 3 inches per hour are used, as is customary in measurement of electric power, for instance.

Consequently, it is suggested that consideration be given to using normal-speed recorders rather than high-speed recorders, in the interest of producing a more legible and considerably less expensive record than could be secured by the use, for instance, of exceptionally high chart speeds so as to resolve the record sufficiently to make its rapid variations clearly legible.

Wherever possible, the signal required for control purposes should be transmitted directly to the controller, without having to be retransmitted from a recorder. The recorders then are used only for their usual functions, namely, producing legible and continuous records of the quantities measured.

Perry A. Borden (The Bristol Company, Waterbury, Conn.): Although the combination of the thermal wattmeter network with differentially connected thermocouples to obtain a d-c effect proportional to a-c power has been known for 60 years, it is interesting to note that the device described by Mr. Downing represents only the third embodiment of this principle to have been developed to what may be called a practical form for the measurement of commercial power. The earlier two, both mentioned in this paper, were introduced in 1926 and 1940 respectively. In fact, the latter of these was first publicly described by Mr. J. H. Miller in his classical paper[1] at the Summer Meeting of the Institute, held in this place just nine years ago. Despite the wide and important application which has been made of the thermal wattmeter principle in telemetering and totalizing, as well as in demand measurement, our textbooks have given it little attention; and in the most recent (1946) edition of Encyclopedia Britannica the subject is dismissed with a scant two lines.

The Lincoln thermal converter, as pointed out by Mr. Downing, is characterized by a relatively long time interval of response, this being due both to the mass of material whose temperature must follow each variation in the measured magnitude and to the unavoidable thermal insulation between heaters and thermocouples. Also, this device is known to have a high internal resistance, with a correspondingly low power output and consequent limitation of practical measurement of its d-c potential to null methods.

The "Thermoverter," described in Mr. Miller's 1940 paper, is characterized by a rapid response—of the order of 1/2 second for 90 per cent of the final reading—and also by a reasonably high power output, making possible under some conditions the determination of output potentials with a direct-deflecting millivoltmeter of the switchboard type. Since the temperature rise of the heaters tends to be proportional to the square of the current which they carry, instruments of the thermal type are especially subject to damage by abnormal currents, as would result from short circuits or other faults in the line under measurement.

While the high thermal inertia of the Lincoln converter tends to offset this susceptibility to damage, it has been found necessary in the low-inertia unit described by Mr. Miller to meet such conditions "artificially," by designing the current transformers which form a part of the instrument in such a manner that their cores become saturated at a current value somewhat above the working range of the device, thus eliminating from the heaters the flow of a secondary current of objectionable magnitude.

In the light of the foregoing comments, we should have further information on the following two points:

1. As a criterion of practical application under normal conditions of use with a null-type recorder, and also as an indication of its adaptability to use with direct-deflecting instruments, it would be of interest to know the resistance value of the output circuit of the new converter, and also the maximum milliwatts available when supplying a matched external impedance.
2. What provision, if any, is made for protection of the heating elements against damage by abnormal currents?

Reference

1. See reference 9 of the paper.

William C. Downing, Jr.: In reply to Mr Borden's question as to the d-c circuit resistance of this thermal converter, the major portion of the resistance is in the potential dividers provided for the adjustments and therefore is dependent upon the position of these adjustments. For a single thermal converter element, with output ratio of approximately 30 millivolts for 500-watts input, the resistance of the d-c output circuit would be between 1 ohm and 7 ohms.

This converter is designed primarily for use with recording or indicating potentiometers. For use with indicating instruments of the d'Arsonval type, where a somewhat lower degree of accuracy might be acceptable than with the potentiometer, the E^2 and I^2 adjustments may be omitted and the output ratio adjustment modified so that the d-c circuit resistance might be of the order of 2 ohms.

It is quite true, as Mr. Borden states, that the older type Lincoln thermal converter obtained some degree of protection on heavy overloads of short duration due to its thermal inertia. However, where it has been necessary to meet specifications of ability to withstand 35 times rated current for 1/2 second, we have for a good many years supplied these converters with a saturable reactor shunted across the current element. In this new thermal converter, the saturable reactor is unnecessary as the design requirements of the current transformer, to give adequate phase angle accuracy, automatically give protection to the converter through saturation of the current transformer core. Incidentally, it may be shown, I believe, that the best that either an ideal saturable reactor or saturable current transformer can accomplish is to reduce the heating effect so that it approaches the first power, rather than the square, of the line current.

Heat Flow Ratio as a Design Parameter in Thermal Demand Meters

J. S. NELSON
ASSOCIATE AIEE

THE time of response of demand meters is of critical importance wherever a demand charge is made for electricity. In demand meters of the mechanical, block-interval type the demand interval is usually governed by a gear train and resetting mechanism connected with some synchronous device, such as a clock motor, and response time presents no special problems in design. The response time of thermal meters depends upon less-easily evaluated constants and coefficients. This paper examines these factors and presents equations from which the time of response may be calculated.

Specifically, these equations pertain to a thermal meter designed with opposed, self-heated, bimetallic spirals connected by a shaft. The effect of relative heat flow from the two opposing bimetallic actuators upon the time constant of a thermal demand meter is explored. To accomplish this, the time equation for a device responding to the difference in temperature of two similar bodies connected by a thermal shunt and each supplied with constant heat input is derived for the general case wherein the heat flow from one of the bodies is not equal to that from the other, that is, heat flow ratio other than unity.

This approach has yielded valuable information pertaining to the effect of differential heat escape upon response time. By making use of these equations, a linear-scale meter (for watt demand) and a square-law scale meter (volt-ampere demand) have been designed for the same response time to meet the same meter code requirement without the necessity for different designs of bimetallic spirals. The significance of this becomes clear when it is recalled that response time is defined in the Code for Electricity Meters[1] as time to reach 90 per cent of ultimate indication (in watts or volt amperes). Hence if two meters having different scale distribution are to meet the same code requirements, their physical response times, in terms of angular deflection, must differ correspondingly.

It is hoped that these equations may find application also to the design of integrating or indicating instruments employing thermal storage such as I^2T indicators for welding energy, small panel instruments of the bimetallic spiral variety, and differential thermometers composed of pairs of resistance-temperature detectors, bourdon tubes, thermocouples, or bimetallic actuators.

Although the effects described may be appreciated intuitively, mathematical equations are developed concurrently with the text for precision and clarity. A complete listing of the symbols used in this analysis, together with their relationships, is shown in Appendix I.

While it is not the purpose of this paper to examine electrical rates and metering methods, it is felt that a brief explanation of the purpose and operation of demand meters will be helpful in orienting the general reader with respect to the device serving as the subject for this analysis.

The demand of an installation or system is the load at the receiving terminals averaged over a specified interval of time.[2] This average may be a simple arithmetic average such as obtained with mechanical, block-interval meters or it may be a continuous logarithmic average[3] as obtained with a thermal demand meter of suitable design. In either type of metering, the information used for billing purposes is usually the maximum demand recorded between meter readings, which is combined with the kilowatt-hour consumption in a formula determined by the particular rate structure in effect. Rate structures with penalty clauses based on demand are used in many localities, in an effort to apportion more equitably the cost of providing generating and distributing capacity adequate for peak loads on the system.

The demand interval is usually made generous in length to avoid penalizing a customer unduly for normal heavy starting loads and other momentary peaks. A typical demand interval is 15 minutes.

Registration of maximum demand is accomplished normally by means of a pointer which can be driven only in the upscale direction by the action of the meter. The position of this pointer at the end of the month (or other billing period) is noted by the meter reader, who then resets it to zero or to the current position of the driving means. The driver, or pointer pusher, is itself a pointer, indicating the demand on a system at any instant (averaged over the current demand interval) for the convenience of the customer and for use in checking the operation of the meter.

Watt-demand and volt-ampere demand are frequently the basis for demand charges. The present paper deals with an assembly, the thermal unit, which may be used as the primary detector for measuring either quantity. The associated electrical circuit is designed to supply this unit with electric currents which are functions of the quantity measured.[3,4] The thermal unit combines the heating effects of these currents and translates these effects into a pointer position that is the proper function of the current flowing and the time during which it flows. It is

Paper 49-160, recommended by the AIEE Instruments and Measurements Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer General Meeting, Swampscott, Mass., June 20–24, 1949. Manuscript submitted March 21, 1949; made available for printing April 29, 1949.

J. S. Nelson is with the Meter and Instrument Divisions, General Electric Company, West Lynn, Mass.

The author is indebted to the authors of references 3 and 5, shown at the end of the paper, whose analyses have been extended to the more general case of unequal heat escape from the two bodies.

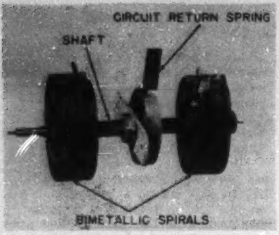

Figure 1. Basic thermal mechanism for demand metering

the purpose of this paper to demonstrate how small changes in thermal geometry may be used to effect differing time functions for this thermal unit and analogous thermal systems.

Analysis

The analysis presented is based on the performance of the thermal unit, Figure 1, which is used for thermal watt demand[3] and thermal volt-ampere demand metering.[4] This unit is composed essentially of two bimetallic spirals mounted on the same shaft in such a manner that increasing temperature in the two spirals produces opposing torques on the shaft. The angular position of the shaft at any time is therefore a function of the difference in temperature of the two spirals. The circuit is such that the current in spiral number 1 is greater than the current in spiral number 2 for up-scale deflection of the associated pointer. The shaft is of thermally conductive material and at a point between the two active spirals is a circuit-return spring connected to a copper lead whose thermal conductance accounts for a significant portion of the total heat loss from the assembly. If this spring is not located at the center point, it will conduct away relatively more heat from the nearer spiral. Similar differences in heat flow may be effected by varying the sizes of the wires connected to the spirals or the characteristics of the insulating shrouds. This relative heat flow, or, more precisely, the relative heat escape, expressed as a ratio, is a useful design parameter.

The utility of heat-escape ratio as a design parameter is not limited to cases of bodies of equal mass, but to avoid complication, M, the heat stored per degree of temperature, is assumed to be the same for the two bodies (bimetallic spirals). The thermal conductance from spiral number 1 to the ambient is denoted by h_1,[*] and h_2 represents the thermal conductance from spiral number 2. H_1 and H_2[*] are the rates of heat developed in (or supplied to) the two spirals, respectively, and Q is the thermal conductance of the connecting means (principally the shaft). θ_1 and θ_2 are temperature increments in the spirals resulting from the application of current to the meter. θ_{01} and θ_{02} are the initial temperatures at the beginning of the period under study, expressed in degrees above ambient temperature.

The heat input to spiral number 1, less the heat being lost down the shaft and by other means to spiral number 2, must at any instant equal the heat escaping to ambient added to the heat being stored in the spiral. In symbols

$$H_1dt-Q(\theta_1-\theta_2+\theta_{01}-\theta_{02})dt \\ =h_1(\theta_{01}+\theta_1)dt+Md\theta_1 \qquad (1)$$

and similarly,

$$H_2dt+Q(\theta_1-\theta_2+\theta_{01}-\theta_{02})dt \\ =h_2(\theta_{02}+\theta_2)dt+Md\theta_2 \qquad (2)$$

At some loss in generality, the solution to this pair of equations may be simplified by letting $\theta_{01}=\theta_{02}=\theta_0$. This limits the specific analysis to the case of initial equilibrium of the thermal unit, with pointer indicating zero, and with ambient temperature constant.

$$H_1dt-Q(\theta_1-\theta_2)dt=h_1(\theta_0+\theta_1)dt+Md\theta_1 \qquad (1a)$$

$$H_2dt+Q(\theta_1-\theta_2)dt=h_2(\theta_0+\theta_2)dt+Md\theta_2 \qquad (2a)$$

The substitution in equation 2a of the value of θ_2 and its derivative from equation 1a yields a second-order differential equation in θ_1

$$\frac{d^2}{dt^2}\theta_1+A\frac{d}{dt}\theta_1+B\theta_1=C-B\theta_0 \qquad (3)$$

wherein A, B, and C are shorthand for combinations of the primary design constants of the system (see Appendix I). By primary design constants are meant those constants such as mass, conductivity, thermal capacity, and so forth, which are controllable in design. The general solution may be obtained by the method of Euler and d'Alembert as follows

Let m be such that $\theta_1=\epsilon^{mt}$.

Substituting

$$m^2\epsilon^{mt}+Am\epsilon^{mt}+B\epsilon^{mt}=C-B\theta_0$$

from which is obtained the auxiliary or characteristic equation

$$m^2+Am+B=0$$

from which, by the quadratic formula

$$m=\frac{-A\pm\sqrt{A^2-4B}}{2}$$

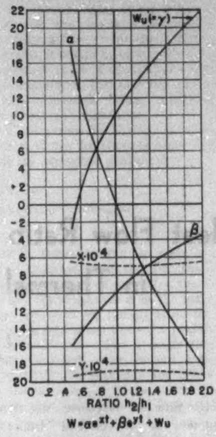

Figure 2. Effect of heat-escape ratio on thermal-unit coefficients

and the general solution may be written

$$\theta_1=c_1\epsilon^{\frac{-A+\sqrt{A^2-4B}}{2}t}+c_2\epsilon^{\frac{-A-\sqrt{A^2-4B}}{2}t}+c_3 \qquad (4)$$

wherein c_1, c_2, and c_3 are constants of integration.

An exactly analogous process yields the solution for θ_2:

$$\theta_2=c_1{}'\epsilon^{\frac{-A+\sqrt{A^2-4B}}{2}t}+c'_2\epsilon^{\frac{-A-\sqrt{A^2-4B}}{2}t}+c_3{}' \qquad (5)$$

It will be recalled that the angular position of the shaft and pointer is a function of the temperature difference, W, of the two spirals. Defining W as $\theta_1-\theta_2$, performing the subtraction, and introducing more shorthand to combine the integration constants

$$W=\alpha\epsilon^{\frac{-A+\sqrt{A^2-4B}}{2}t}+\beta\epsilon^{\frac{-A-\sqrt{A^2-4B}}{2}t}+\gamma \qquad (6)$$

rewritten for convenience.

$$W=\alpha\epsilon^{xt}+\beta\epsilon^{yt}+\gamma \qquad (7)$$

The only variables in equation 7 are W and t. This then is an expression for instantaneous temperature difference as a function of time. It remains to evaluate the constants α, β, and γ in terms of primary design constants.

Evaluation of Constants

The Constant γ

In equation 7, the exponent of ϵ may be

---

[*] See Appendix I for definition.

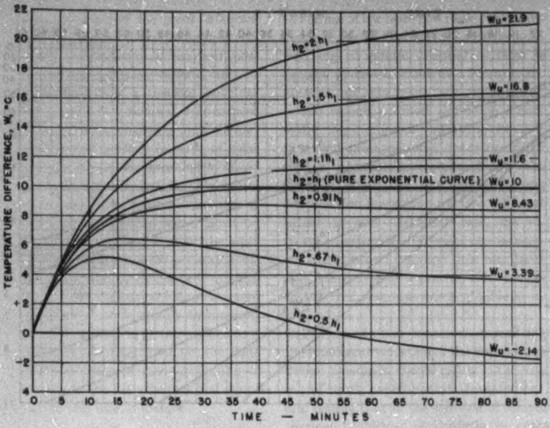

Figure 3. Calculated effect of heat-escape ratio on thermal unit time-performance curve

demonstrated negative for all real values. Hence at $t=\infty$, $W=\alpha\epsilon^{-\infty}+\beta\epsilon^{-\infty}+\gamma,=\gamma$; or, $W_{t=\infty}=\gamma=$(by definition) W_u, ultimate temperature difference.

From equation 3 and the analogous equation in θ_2, it is easy to find the ultimate values of θ_1 and θ_2, their difference, W_u, being rendered as

$$W_u=\frac{h_2H_1-h_1H_2}{Q(h_1+h_2)+h_1h_2} \tag{8}$$

In the special case where $h_1=h_2=h$

$$W_u=\frac{H_1-H_2}{2Q+h} \tag{9}$$

the same equation derived directly for this case in the literature.[4,5]

THE CONSTANTS α AND β

A new boundary condition is needed for the evaluation of the constants α and β. Before any heat can be lost from a body at room temperature, a temperature gradient must be established. If this hypothetical body has a finite heat capacity and a sudden input is applied, these two factors will, as t approaches zero, govern the rate of temperature rise.

This line of reasoning gives the equations

$$\left.\frac{d\theta_1}{dt}\right|_{t=0}=\frac{H_1}{M} \text{ and} \tag{10}$$

$$\left.\frac{d\theta_2}{dt}\right|_{t=0}=\frac{H_2}{M} \tag{11}$$

from which

$$\left.\frac{dW}{dt}\right|_{t=0}=\frac{H_1-H_2}{M} \tag{12}$$

Letting $W=0$ at $t=0$, from equation 7 is derived

$$\alpha+\beta=-\gamma \tag{13}$$

Differentiating equation 7 yields

$$\frac{dW}{dt}=x\alpha\epsilon^{xt}+y\beta\epsilon^{yt} \tag{14}$$

At $t=0$,

$$\left.\frac{dW}{dt}\right|_{t=0}=x\alpha+y\beta \tag{15}$$

Equating equations 12 and 15 and solving simultaneously with equation 13 yields β and α

$$\beta=\frac{h_2H_1-h_1H_2}{Q(h_1+h_2)+h_1h_2}\times\left(\frac{h_1+h_2+2Q-\sqrt{(h_1-h_2)^2+(2Q)^2}}{2\sqrt{(h_1-h_2)^2+(2Q)^2}}\right)-\frac{H_1-H_2}{\sqrt{(h_1-h_2)^2+(2Q)^2}} \tag{16}$$

$$\alpha=-\frac{h_2H_1-h_1H_2}{Q(h_1+h_2)+h_1h_2}-\frac{h_2H_1-h_1H_2}{Q(h_1+h_2)+h_1h_2}\times\left(\frac{h_1+h_2+2Q-\sqrt{(h_1-h_2)^2+(2Q)^2}}{2\sqrt{(h_1-h_2)^2+(2Q)^2}}\right)+\frac{H_1-H_2}{\sqrt{(h_1-h_2)^2+(2Q)^2}} \tag{17}$$

The exponents x and y were developed previously and their expanded forms are listed in Appendix I.

The fundamental equation of the thermal unit, equation 7, may now be expressed in terms of primary design constants. These constants, namely heat input, heat escape, thermal conductance, and thermal capacity, are all under the control of the designer and when these values are known thermal unit response may be predicted. As has been pointed out, when the heat-escapes from the two spirals are made equal a well-known result is obtained, equation 9, and when the thermal conductance between the bodies is reduced to zero, equation 7 reduces to an expression wherein the terms involving body 1 and body 2 are separated, as would be expected.

Interpretation of Results

The coefficients in the expression for temperature difference are presented graphically in Figure 2, and the performance of thermal units designed with such coefficients is illustrated in the succeeding figures. The shape and disposition of these curves is of greater interest than the numerical values, which are arbitrary.

The Ideal Design Parameter

The ideal design parameter, academically speaking, is one which influences only one characteristic of the device. The designer or experimenter can vary this parameter to produce a desired result with no effect on any other characteristic, and such a parameter is a very effective tool.

At first glance the parameter M, heat capacity, appears to fulfill the requirements for an ideal parameter. It appears only in the exponential terms and not in the expression for ultimate value. This appearance is illusory, at least with regard to the thermal mechanism of Figure 1, for practically it would be very difficult to change the heat capacity without affecting also the heat-escape properties, the electrical resistivity, or the thermal deflection properties of the bimetallic spirals.

On the other hand, the construction of Figure 1 affords a ready means of varying another parameter, namely heat-escape ratio, with relatively small effect upon the other design constants of the thermal unit, provided the changes in heat escape ratio are kept small. Quite significant changes in performance may be effected simply by placing the circuit return spring a short distance to left or right of the midpoint of the shaft. In order to appreciate the advantages and limitations of this parameter as a design tool, it is well to examine the effects of wide variations in h_2/h_1.

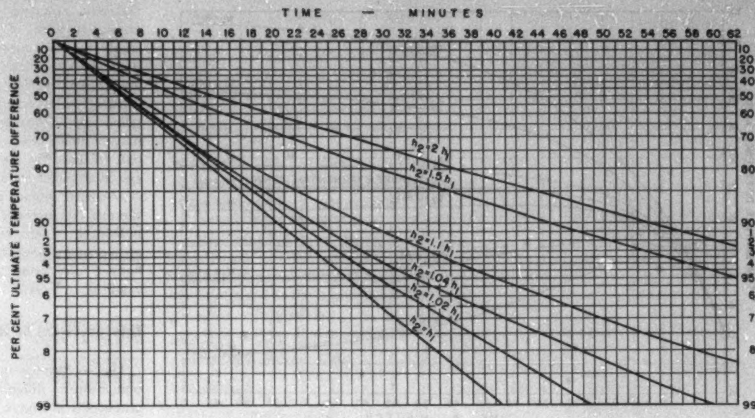

Figure 4. Per cent ultimate temperature difference as a function of time

Effects of Varying the Heat-Escape Ratio

The major effect of changing the design parameter h_2/h_1 is to operate upon the coefficients of the equation, the exponents x and y being very little affected by large changes in heat-escape ratio, Figure 2.

Referring again to Figure 2, it may be seen that selecting a heat-escape ratio other than unity is, to a first approximation, equivalent to adding or subtracting a definite fraction of a temperature increment that follows a different exponential curve from that at unity ratio. By adjusting the proportions of the two exponential terms through appropriate selection of the heat-escape ratio, various overall times of response may be attained, Figure 5. In cases of systems not required to approximate a simple exponential curve, a range of response times varying by a factor of ten or more may be achieved by doubling the heat-escape ratio.

Four categories of heat escape ratio are of interest and will be commented upon:

Ratio unity: A simple logarithmic curve results.

Ratio small: Temperature difference will lessen or reverse with time.

Ratio large: Response time is increased, but time constant is rendered complex.

Ratio slightly larger than unity: Response time may be controlled with the least effect upon other characteristics.

UNITY RATIO

Referring to Figure 2, the coefficient, α, of the first term has become zero and the coefficient, β, of the second term is equal numerically, but opposite in sign, to W_u, the ultimate temperature difference. A thermal unit designed with these coefficients will approach the value shown in equation 9 along a simple exponential curve with time (see Figure 3, curve labeled $h_2=h_1$). This performance curve is ideal for a demand meter indicating a continuous logarithmic average.[3]

SMALL RATIO

At values of heat-escape ratio less than unity the performance curve will overshoot, Figure 3, or dip, a condition to be avoided particularly in demand meters which contain maximum demand pointers. In indicating instruments such a condition is analogous to underdamping and is less serious the shorter the time required to reach the designed indication.

At very small values of h_2/h_1, W_u becomes negative, corresponding to an ultimate deflection in the direction governed by the spiral receiving the less input.

LARGE RATIO

A thermal mechanism designed with heat-escape ratio equal to or greater than unity will not overshoot, Figure 3. The response time increases with increasing ratio as depicted in Figure 5, which was plotted from the intersection of the curves in Figure 4 with the 90 per cent line. The ultimate difference also increases with h_2/h_1, as shown in Figures 3 and 5, so that no independent adjustment of response time is possible. At values greater than unity the performance does not follow a simple exponential curve, for two exponential functions are involved. In this connection note the departure from linearity of the response curves plotted on semilogarithmic co-ordinates, Figure 4, at ratios other than unity. If this "trailing off" is great enough, the result is known as "creeping"[3] which is, of course, objectionable in measuring devices.

RATIO SLIGHTLY LARGER THAN UNITY

The region between 1.0 and 1.1 or less is the useful area for demand meter thermal-unit design. In this region, a wide variation in response time may be obtained without the objectionable creep that results from the introduction of too large a portion of a second exponential term. As noted before, the unit cannot overshoot when h_2/h_1 is greater than unity. The value of deflection response time is very sensitive to variations in heat-escape ratio near unity, Figure 5, and it is in this region that heat-escape ratio partakes to the greatest extent of the characteristics of an ideal parameter. The change in heat-escape ratio necessary to produce a 10 per cent change in response time from the value at unity ratio will produce only a 4 per cent change in ultimate deflection or sensitivity of the thermal unit. As the thermal conduction path from a spiral through the shaft to the circuit return spring, Figure 1, is an important source of heat escape, a dislocation of the circuit return spring will cause a significant change in heat-escape ratio without materially affecting total heat escape. It may be seen from equation 8 that any change in the material or cross-section of the shaft which reduces h_1 and h_2 will increase the sensitivity or ultimate deflection of the thermal unit. This effect is made more pronounced by the reduction in Q accompanying such a modification. Because of the great influence of shaft design upon the response time and thermal unit sensitivity, it has been possible to adapt one basic thermal unit to the requirements of a thermal watt demand meter and a thermal volt-ampere demand meter by changing only the design of the shaft, which is made of solid brass in the former instance and of stainless steel tubing in the latter. The inherent or angular deflection response time of the volt-ampere demand meter must be materially greater than that of the watt demand meter, because 90 per cent indication occurs at only 81 per cent angular deflection when indication follows a square law. The bimetallic spirals themselves, the circuit return springs, the cups, covers, shrouds, and end shields remain the same for the two units, a standardization of great value in the manufacture and maintenance of this line of meters.

Summary

The role of heat-escape ratio in the performance of thermal units for demand metering has been illustrated. The curves presented were calculated with the use of arbitrary, although reasonable values for the design constants and do not in all cases agree with values chosen for the final designs of the thermal unit. The actual ratio of h_2 to h_1 also is affected by the lower temperature-rise-per-watt at higher temperatures, a radiation phenomenon neglected in the computation of these curves. These curves do, however, give a qualitative picture of the effect of varying the heat-escape ratio.

The use of the heat-flow ratio parameter in the design of thermal units for demand metering or similar thermal systems is subject to two limitations: First, it influences not only response time but also, to less extent, ultimate deflection. Secondly, this method of controlling response time will produce some departure from simple exponential response. In the example cited, one thermal unit was adapted for measuring at two different rates. In this particular case, the increase in ultimate deflection accompanying the increased response time was desirable and the small departure from simple exponential response was negligible in its effect.

The use of these equations, permitting the intelligent variation of the appropriate design constants, should result in the saving of much experimental, development, and testing time in the solution of related thermal problems, particularly in cases where it is desired to adapt one basic assembly to different times of response.

Appendix I. Definitions of Symbols and Their Relationships

H_1 = rate of heat applied to spiral number 1, in gram-calories per second

H_2 = rate of heat applied to spiral number 2 (exclusive of that received by conduction from spiral number 1), in gram-calories per second

h_1 = thermal conductance from spiral number 1 by all paths to ambient (exclusive of the path from spiral number 1 through the connecting means to spiral number 2) (gram-calories per second per degree centigrade)

h_2 = thermal conductance by all paths from spiral number 2 to ambient (gram-calories per second per degree centigrade)

Q = thermal transfer coefficient of shaft, or rigorously, heat transferred from one spiral to the other by all paths (gram-calories per second per degree centigrade)

θ_{01} = initial temperature of spiral number 1, degrees centigrade above ambient

θ_{02} = initial temperature of spiral number 2, degrees centigrade above ambient

θ_1 = instantaneous temperature of spiral number 1 above θ_{01} (degrees centigrade)

θ_2 = instantaneous temperature of spiral number 2 above θ_{02} (degrees centigrade)

M = thermal capacity of each spiral (assumed equal) (gram-calories per degree centigrade)

$$A=\frac{h_1+h_2+2Q}{M}$$

$$B=\frac{Q(h_1+h_2)+h_1h_2}{M^2}$$

$$C=\frac{Q(H_1+H_2)+h_2H_1}{M^2}$$

$$C'=\frac{Q(H_1+H_2)+h_1H_2}{M^2}$$

c_1, c_2, c_3 and c_1', c_2', c_3': integration constants evolving α, β, and γ

W = instantaneous temperature difference = $(\theta_1+\theta_{01})-(\theta_2+\theta_{02})$

$\gamma=c_3-c_3'$, a constant of integration, evaluated as W_u

ϵ = base of Napierian logarithms

$$x=\frac{-A+\sqrt{A^2-4B}}{2}$$

$$=-\frac{h_1+h_2+2Q-\sqrt{(h_1-h_2)^2+(2Q)^2}}{2M}$$

$$y=\frac{-A-\sqrt{A^2-4B}}{2}$$

$$=-\frac{h_1+h_2+2Q+\sqrt{(h_1-h_2)^2+(2Q)^2}}{2M}$$

t = time measured from application of load (seconds)

$\beta=c_2-c_2'$, a constant of integration evaluated as follows:

$$\beta=\frac{h_2H_1-h_1H_2}{Q(h_1+h_2)+h_1h_2}\times\left(\frac{h_1+h_2+2Q-\sqrt{(h_1-h_2)^2+(2Q)^2}}{2\sqrt{(h_1-h_2)^2+(2Q)^2}}\right)-\frac{H_1-H_2}{\sqrt{(h_1-h_2)^2+(2Q)^2}}$$

In special cases

$$\beta\Big|_{h1=h2=h}=-\frac{H_1-H_2}{2Q+h}$$ (value at unity heat-escape ratio)

$$\beta\Big|_{Q=0}=-\frac{H_1}{h_1}$$ (value for an isolated spiral)

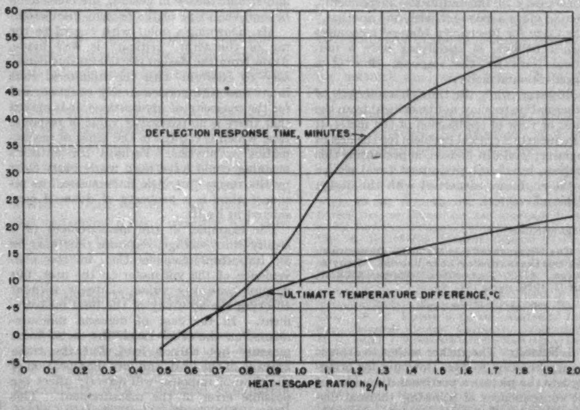

Figure 5. Response time and ultimate temperature difference as functions of heat-escape ratio

$\alpha = c_1 - c_1'$, a constant of integration evaluated as follows:

$$\alpha = -\frac{h_2H_1 - h_1H_2}{Q(h_1+h_2)+h_1h_2} - \frac{h_2H_1 - h_1H_2}{Q(h_1+h_2)+h_1h_2} \times \left(\frac{h_1+h_2+2Q-\sqrt{(h_1-h_2)^2+(2Q)^2}}{2\sqrt{(h_1-h_2)^2+(2Q)^2}}\right) + \frac{H_1-H_2}{\sqrt{(h_1-h_2)^2+(2Q)^2}}$$

In special cases

$$\alpha\Big|_{h_1=h_2=h} = 0 \text{ (value at unity heat-escape ratio)}$$

$$\alpha\Big|_{Q=0} = \frac{H_2}{h_2} \text{ (value for an isolated spiral)}$$

The fundamental equation 7:

$$\left.\begin{aligned} W &= \alpha\epsilon^{xt}+\beta\epsilon^{yt}+W_u \\ &\text{or,} \\ W &= -\alpha(1-\epsilon^{xt}) - \beta(1-\epsilon^{yt}) \end{aligned}\right\} \text{(Where } x \text{ and } y \text{ are; negative constants the only variables, } W \text{ and } t)$$

The ultimate temperature difference (full-scale value)

$$W_u = \gamma = -(\alpha+\beta) = \frac{h_2H_1 - h_1H_2}{Q(h_1+h_2)+h_1h_2}$$

Discussion

Wm. C. Downing, Jr. (Sangamo Electric Company, Springfield, Ill.): In presenting his excellent analysis of the effects of thermal dissymmetry on the time of response of thermal demand meters, Mr. Nelson has made a worthwhile contribution to the literature on this subject. While these general principles have been appreciated, in the past, and have been employed to control the response time characteristics of thermal meters, there has not been available, to my knowledge, any such quantitative analysis. This paper, therefore, should provide a valuable reference for future work in this field.

While the heat flow ratio has been selected as the parameter for this analysis, it is inferred that a comparable set of equations might be developed based upon the thermal capacity ratio as a parameter, the heat flow ratio being unity. In other words, the time of response also may be controlled by unbalancing the heat storage factors instead of the heat flow. Practical considerations, based on constructional features, normally determine the choice of one of these methods, or a combination of them; for, while it is quite true that it is difficult in general to unbalance the thermal capacity without disturbing the heat flow ratio, unbalancing of the heat flow ratio must be used with caution to avoid the introduction of errors which may be of much more importance than the time characteristic. As this latter point is not considered in this paper, it may be well to amplify it.

Let us assume, for example, a thermal watt demand meter in which the heat flow ratio is 1.1. If for a certain load, H_1 is 3 watts and H_2 is 1 watt, the numerator of the expression for W_u, equation 8, is $3.3-1$, or 2.3. For the same power measured, but at a different power factor, for example, H_1 might be 4 watts and H_2 2 watts, since the electrical circuit provides only that the difference between H_1 and H_2 remains proportional to the power measured; however, in this latter case, the numerator of equation 8 becomes $4.4 - 2$, or 2.4. As W_u should be alike in these two cases, the introduction of a heat flow ratio other than unity has introduced an error in meter registration. This would appear to be a more serious limitation to the use of heat flow ratio as a parameter than either of those mentioned in the paper.

Actually, of course, some such "error" may be desirable to compensate for the tendency of the temperature-rise-per-watt to decrease when the total power input is increased as in the foregoing example, and watt demand meters have been built for years with a heat flow ratio slightly greater than unity for this reason. Nevertheless, it may be argued that the importance of the heat flow ratio in minimizing power factor, voltage, or balance errors should dominate, in design, its effect on time of response.

In only one respect, however, would I question Mr. Nelson's paper and that is in reference to the opening statement that "the time of response of demand meters is of critical importance." Insofar as the timing accuracy of a demand register is concerned, this is quite true; but I believe it has been rather well established by a number of independent surveys that whether the time interval is 15 minutes or, say, 20 minutes, for either a demand register or a thermal demand meter, makes negligible difference in the billing of the great majority of demand loads. For one such reference, refer to P. A. Borden's paper presented before the Institute in 1920[1]; "Except upon the most fluctuating loads, the demand meters of one type, and of differing time periods give indications which, generally, within the limits of accuracy of the individual instruments, were in close agreement with one another." The Code for Electricity Meters[2] recognizes this, I believe, in specifying only a unilateral limit for the response time of a lagged-demand meter.

However, while the time characteristic of a thermal meter may not be critical from the point of view of application of the meter, it is frequently a critical problem for the design engineer; and Mr. Nelson, in presenting this analysis, has, I feel, performed a real service to the engineers concerned with the design of thermal meters.

J. S. Nelson: The author wishes to express his appreciation to Mr. Downing for bringing into the picture a pertinent discussion of the consequences of allowing thermal dissymmetry to affect ultimate deflection. He states that "the electrical circuit provides only that the difference between H_1 and H_2 remain proportional to the power measured," and deduces therefrom certain errors in registration at different levels of spiral energization. In this connection it is well to point out that, in certain instances, circuit elements may be provided with resistance characteristics such that the expression proportional to the quantity measured is not $H_1 - H_2$, but $kH_1 - H_2$, where k is a constant containing the parameter h_2/h_1. A circuit designed for such proportionality in the measurement of volt ampere demand has been described in a previous paper before the Institute by Douglass and Morong.[1]

Mr. Downing's reservation may therefore be regarded as particular, rather than general, specifically applying to the use of unbalanced heat escape in thermal watt demand meters, and with this reservation the writer is in full agreement. In a family of meters using the same basic thermal motor, the watt demand meter should be assigned the position at or nearest unity ratio. Power factor errors still present may be compensated successfully by the appropriate relationship between the resistances of the upscale and downscale bimetallic spirals, which resistances are themselves functions of temperature and current. The design criteria for accomplishing this compensation, and circuit theory in general, are considered beyond the scope of the present discussion.

Mr. Downing's point with regard to the use of the term "critical" is well made. Aside from the design considerations necessary to conform with the unilateral code limits and with good metering practice, and for the majority of applications, it is agreed that there is no particular value of response time which is critical in the sense of mathematics or physics. Perhaps the author's meaning could have been made more clear by the terms "intrinsic importance," as response time is a property of demand considered in itself.

For example, in the measurement of a steady-state voltage, response time may be an important consideration in the convenience of the voltmeter to the user, but it may have any value whatever without effecting the accuracy of the final measurement. In the case of demand measurements, on the other hand, the meter must measure not only a load, but the time-average of the load, and any modification of the time of response will directly affect the possible error of the measurement. This means that, in the ideal, the time of response is just as critical as the demand measurement itself (but no more so). If a 15-minute demand interval meter produces the same maximum reading as a 20-minute demand interval meter connected to the same terminals, it must be due to the fortuitous circumstance that the system had equal 15-minute and 20-minute maximum demands during the period of the test. Happily, as Mr. Downing points out, this ordinarily will be the case, and this fact should be recognized in the application of thermal demand meters.

An Improved A-C Network Analyzer

W. A. MORGAN
MEMBER AIEE

F. S. ROTHE
MEMBER AIEE

J. J. WINSNESS
NONMEMBER AIEE

SINCE the first a-c network analyzer was installed in 1929 at the Massachusetts Institute of Technology,[1] it has become the accepted tool for the solution of the complex circuit problems involved in the design, planning, and operation of power systems. There are now over 20 a-c network analyzers in the United States[2] and several more built or planned in Canada, England, Europe, South America, and India. Many of these analyzers are used by a number of different groups on a rental or co-operative basis. The improvements in design and performance of the analyzer which are described in this paper will thus be of interest to a large number of users of such equipment. These improvements include: master instruments which read power and reactive flows directly in megawatts and megavars for any one of three system megavolt-ampere bases and on any one of six current scales; a complete set of generator instruments which allows volts, megawatts, and megavars to be preset; load-adjusting autotransformers with voltmeters, which permit the system loads to be held constant without reference to the master instruments; a flexible method for the exact representation of a transmission line by means of an equivalent circuit; push button selection of circuits to be metered, either singly or in groups; and complete factory wiring, assembly, and testing. An analyzer of this improved design recently has been installed at the United States Bureau of Reclamation in Denver, Colorado.

Value of the A-C Network Analyzer

There are several reasons for the acceptance of the a-c network analyzer as a tool in solving power-system problems. In contrast with numerical calculating machines, it uses voltage, current, and impedances to solve the problem. Thus a power system covering several states can be represented realistically on an analyzer in a medium-sized room by simply replacing the elements of the power system with electric circuits. The power engineer is familiar with the use of equivalent circuits for such elements as synchronous machines, transformers, and transmission lines. By the use of equivalent circuits a variety of problems in electromagnetic fields, vibration, heat flow, and other subjects also have been solved on network analyzers.[3]

The modern a-c network analyzer is a very flexible device. System changes such as a load increase, a line outage, a change in transformer taps, or a change in the supply of reactive power, can be simulated rapidly and their effect found immediately. Since power-system design is based on the collective judgment of several persons, the problem is not one of specifying a set of initial conditions and obtaining a result correct to four decimals but rather a determination by trial and error of the best design based on a number of initial assumptions. The a-c network analyzer is essential for the expeditious study of complicated networks under variable conditions; even on simpler systems the accuracy of a numerical calculator is not necessary.

The first cost of a modern analyzer might seem high, but is actually low in comparison with possible savings in system design. A recent study made on the analyzer of the United States Bureau of Reclamation resulted in the substitution of a single-circuit 115-kv line for over 15 miles of 2-circuit line which had been previously thought necessary. Another saving resulted when it was determined that a synchronous condenser was not needed at an extension of the power system as originally planned.

Perhaps the greatest savings in power-system design, resulting from the use of the a-c network analyzer by the Bureau of Reclamation has been in power-system transient stability studies. Wherever practicable, and where the nature of the load justifies it, it is the policy of the Bureau of Reclamation to design its power systems to be stable for the most severe probable fault conditions. This becomes a determining factor because the Bureau's hydroelectric generation is usually at a long distance from the load centers.

Low generator transient reactance is an important factor in transient stability. However, due to their slow speed, hydroelectric generators normally do not have as low a reactance as steam-turbine generators, and special low reactances are obtained at extra cost. The a-c network analyzer is the best means available to evaluate this extra cost, which would be considerable for a plant such as Grand Coulee with an installed capacity of over 2,000,000 kva.

The value of rapid reclosing of circuit-breakers (12–20 cycle) on transient stability of a power system can be determined accurately in advance only by analyzer studies. Such studies, made in 1944 by the Bureau of Reclamation demonstrated that two 161-kv transmission lines, 140 miles long, with 20-cycle reclosing circuit breakers, were the practical equivalent of three lines without 20-cycle reclosing circuit breakers for the loads involved.[4] Subsequent operation through two complete years of this system, in lightning-active country, proved that the calculating-board studies were accurate. In the future, the important

Paper 49-164, recommended by the AIEE Computing Devices Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer General Meeting, Swampscott, Mass., June 20–24, 1949. Manuscript submitted March 7, 1949; made available for printing April 29, 1949.

W. A. Morgan is in charge of the Power System Technical Section, Bureau of Reclamation, Denver, Colo.; F. S. Rothe is in the Analytical Division, General Electric Company, Schenectady, N. Y.; and J. J. Winsness is in the Switchgear Divisions, General Electric Company, Philadelphia, Pa.

The authors wish to acknowledge the important contribution from H. A. Peterson of the University of Wisconsin, formerly with the General Electric Company, to the general design of the analyzer, and from H. P. Kuehni of the General Electric Company to the design of the master instrument system.

load served by these two transmission lines will be supplied principally from a different direction as new hydroelectric generation sources are developed. At that time the two initial lines are all that are required from a power-flow or stability standpoint from the present source of generation even without dependence upon reclosing circuit breakers. Thus, the application of reclosing circuit breakers for the initial system saved building a 140-mile 161-kv line that would not be required in the ultimate system. It is Bureau of Reclamation practice, in the design of practically all its power systems of 115 kv and above, to utilize to the fullest extent the advantage of ultra-rapid reclosing circuit breakers in transient stability, with the result that the a-c network analyzer will help the Bureau to save many hundreds of miles of transmission lines.

For some important loads an interruption of any kind is a serious matter. Such loads could not tolerate the instability that would result if reclosing on a permanent fault occurred. Thus, in areas where the faults are less likely to be due to lightning and faults due to airplanes and similar hazards are more probable, rapidly reclosing circuit breakers may not be so essential. In these cases, the a-c network analyzer is used to investigate stability of the power system for the condition of faulting and clearing, without reclosing, the most heavily-loaded transmission line section. If rapid reclosing circuit breakers are used on such a system to restore the faulted line section to service as soon as possible, then the a-c network analyzer would be used to determine what must be done to the system to make it stable for the condition of reclosing on a permanent fault and clearing the faulted line a second time.

These are but a few specific examples that show how the a-c network analyzer installed at the Bureau of Reclamation already has paid for itself in design savings.

General Design Features

The best design of an a-c network analyzer should satisfy the requirements of accuracy, flexibility, and reliability at reasonable cost. The choice of the base electrical quantities of voltage, current, and frequency on which the per-unit representation of the power system is made is very important. A small current base and high impedance base result in freedom from heating and contact problems, allow the use of the very reliable telephone-type cords, plugs, and jacks, and permit a wide range in the operation of the units. The first analyzer employing a base current less than 1 ampere was built in 1938.[5] This analyzer used a base voltage of 50 volts, a base current of 50 milliamperes, and a base frequency of 480 cycles. This analyzer has been in continuous use since that date. During the war it was in operation 16 hours a day for two years; since the war it has been operating 60 hours a week until recently. This experience and the small amount of maintenance has shown that the choice of base quantities was sound, and that the design of the board was such as to make it very reliable. The stray capacitances associated with the high impedance base have not been found to be important in system studies. The new analyzer, shown in Figure 1, makes use of such techniques as careful arrangement of wiring and use of low-capacitance switches and relays to make this effect negligible. Therefore, the use of these same base quantities has been continued in the improved analyzer.

Table I shows the number, range, and ratings of the different types of circuit units in the Bureau of Reclamation analyzer. The ranges of units are such that, in the majority of cases, one unit will cover the range required. All of the impedance and transformer units are rated 1.25 per unit volts and 5 per unit current. Their thermal ratings are such that no damage will be done to them at 10 per unit current. Low flux densities and air-gap construction utilized in the reactors results in very little variation in impedance up to 10 per unit current and 1.25 per unit volts. The generator units are rated 2.5 per unit volts and have 2 per cent regulation at 10 per unit current. They are capable of delivering 20 per unit current with slightly higher regulation. These wide operating limits make it possible to handle most problems such as load and short-circuit studies with ease, without spending a considerable amount of time in setting up the system between narrow limits. For extreme conditions, it is possible to reduce the analyzer input voltage to $^1/_2$ or $^1/_4$ normal. With 25 per cent input voltage to the analyzer and 20 times normal current from a generator,

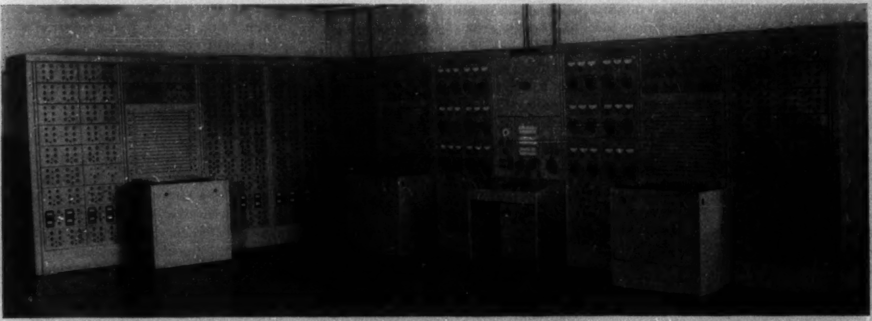

Figure 1. A typical modern a-c network analyzer

The center cabinet of the front section contains the master instruments and associated voltage, current, and push-button selector switches. Adjacent to and on each side of the instrument cabinet is a unit cabinet containing six generator units and six synchronous impedance units. Cabinets 2, 6, and 10 (numbered from left end) are plug-and-jack cabinets in which the terminals of circuit units in two or three adjacent cabinets are brought out for interconnection. The remaining cabinets are unit cabinets containing line, load, autotransformer, capacitor, and mutual transformer units. This analyzer has the front section and left wing with provisions for future addition of a right wing

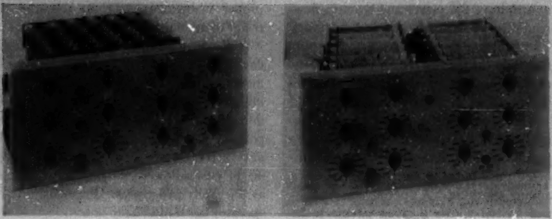

Figure 2. Capacitor-unit and line-unit drawout tray

Line unit with Pi-line switches

a fault current of 80 times the system base can be supplied from any generator unit. This large current range has proved to be very valuable in making system studies.

Tapped resistors, reactors, and capacitors are used in all units, except for the 0 to 0.1 per unit resistance in the load unit, in order to obtain definite fixed values of impedance. The accuracy on all taps down to 0.02 per unit at a specified current is ± 1 per cent, and ± 2 per cent at 0.01 and 0.02 per unit. The change in reactance of the reactors is less than ± 2 per cent over the full current range at any setting.

The impedance and transformer units are mounted on standard 8-inch high by 16-inch wide by 18-inch deep drawout trays. Figure 2 shows typical line-unit and capacitor-unit trays. Two line units or six capacitor units are mounted on one tray as shown. The generator unit is mounted on a double-height drawout tray, as shown in Figure 3. This standardization in tray size permits a standard unit cabinet size and maximum flexibility in arrangement of units and cabinets.

Load Units and Load Adjusters

The load units have individual voltmeters with manually-set pointers, and are connected to the system through individual autotransformers so that the voltage impressed on each unit can be kept constant regardless of changes in system voltage. This is especially helpful during the initial adjustment period, before the transmission line voltage opposite a given load substation has stabilized. The settings of the resistance and reactance values of the load units are calculated previously on the basis of one per unit voltage. If voltages other than one per unit prevail, then the loads would be different from what they are supposed to be, with no change in the load unit settings. The individual voltmeters allow the adjuster to monitor these load units and to keep the voltage at one per unit by adjustment of the one per cent taps of the autotransformer, without reference to the master instruments. It has been found that this feature saves considerable time in making load studies where it is desired to keep the system load constant during variations in the system design.[6]

Generator Units

Each generator unit consists of two selsyns, one for controlling phase angle and the other for controlling voltage magnitude. In addition, each generator unit has its own instrumentation, including a voltmeter, varmeter, and wattmeter, as shown in Figure 3. These instruments have red hand-set pointers that may be used to indicate the conditions under which the generator is expected to operate. A varmeter has been substituted for the ammeter usually found on generator units because watts and vars are of primary interest in adjusting a generator unit during a system study. In order to minimize the load imposed by the instruments on the generator and to decrease their effect on regulation, a current amplifier is used to feed the wattmeter and varmeter. The voltmeter can be connected either at the generator terminals or at any desired bus on the system.

Equivalent Pi-Line Units

Pi-line units have been found to be very useful in making system studies. It is desirable to be able to meter both ends of a pi-line unit and also, if possible, to use the capacitors and line unit individually. The equivalent pi-line unit consists of two standard capacitor units and one standard line unit, with a toggle switch on the line unit to connect a capacitor unit to each end of the line unit. Figure 4 shows the equivalent pi-line circuit. By plugging the capacitor-unit cords for units *300* and *301*, it is possible to read power flow at both ends of the line. Opening the toggle switch permits free and independent use of the line-unit and capacitor-unit sections in any manner desired. This permits having pi-line units without incurring restrictions in flexibility.

Instrument System

The master-instrument system is probably the most important part of a network analyzer. Figure 5 shows the master-instrument control panel, including the master instruments, scale selector switches, voltage and current selector switches, motor-generator-set control switches, reference phase shifter, and push-button selector panel. The master instruments include a voltmeter, ammeter, and wattmeter-varmeter of the light-beam-type, with 8-inch scales having 150 divisions. These instruments have an extremely fast rate of response and are well damped, making possible rapid reading. The burden imposed on the network by these instruments is minimized by the use of current and voltage feedback amplifiers. For the nominal

Table I. Number and Range of Circuit Units

Number	Units	Per Unit Range	Steps	Rating: Per Unit Volts	Rating: Per Unit Amperes
12	Generator unit	V 0—2.5	Continuous	2.5	10.0
		ϕ 0 ± 180 degrees	Continuous

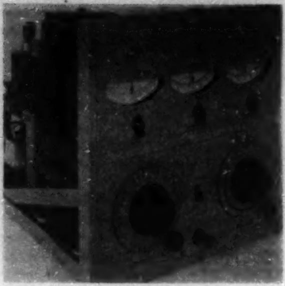

Figure 3. Generator unit

analyzer voltage and current of 50 volts and 50 milliamperes, a maximum potential drop of 0.01 volts (0.02 per cent) across the current shunts and a potential current of 0.1 milliamperes (0.2 per cent) was set as limits of instrument burden. The accuracy of the master-instrument system is within ± 0.5 per cent of full scale.

The scales on the master ammeter and wattmeter are arranged so that the digits appearing at the large scale divisions change with the scale multipliers. The current shunts of the instruments also are changed simultaneously by the knurled-handled scale-selector switch. Thus, the ammeter is direct reading in per unit for any of the six available current multipliers, and the wattmeter is made direct reading either in per unit, or on a 20-megavolt-ampere, 50-megavolt-ampere, or 100-megavolt-ampere base for any of the available current multipliers. This feature is a big improvement, as it allows the operator to change the multiplier readily, for successive metered points if he wishes, so as to get the reading at a favored location on the instrument scale and to have the power and reactive flows read directly in megawatts and megavars. The operator does not have to multiply mentally the reading by a factor to get the actual reading, or remember which of several scales to read.

The master instruments may be connected to meter any circuit selected by means of a 3-column keyboard of numbered push buttons, similar to that of an adding machine. A special master control switch allows a given circuit to be selected by the push buttons while the previous circuit, indicated by the numbered lights adjacent to the push-buttons, is still being metered. This saves time as, while the recorder is putting down the previous reading and the instruments are kept on the previous circuit in case a question should arise, the operator can refer to the plugging diagram, select the next circuit he wishes to meter, and push down the corresponding selector push buttons. Then, when the recorder is ready, the operator pushes the master control switch which connects the instruments to the new circuit and lights the adjacent numbered lights corresponding to the numbered push-buttons, and the operator announces to the recorder which circuit is being metered. While the recorder is locating the new circuit on the diagram, the operator has selected the proper instrument scale to use and is ready to announce the readings.

A special connection of the metering circuit allows the watt and var measurements to be of the proper sign when looking away from a bus, whether the given unit is metered from its polarity or nonpolarity jack plug end. This feature permits faster recording and simplifies checking of power-flow readings around a bus as the study progresses. Previously, the operator has had to keep in mind whether he was metering the polarity or nonpolarity jack plug end of a unit and mentally reverse the sign of the watts or vars from that indicated by the instruments and switches, when appropriate.

The Bureau of Reclamation has taken full advantage of this feature in originating a new method of indicating polarity sign of watt and var readings on power-flow diagrams. This is illustrated in Figure 6. The arrows are made up initially as part of the basic single-line diagram and are for reference only, to show the direction the instruments were looking when the readings were taken. The plus and minus signs in front of the watts (above the line) and vars (below the line) are then the actual signs indicated to be used by the master instruments and polarity switches, referred to the reference arrow direction, which is always away

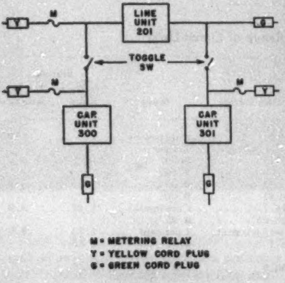

Figure 4. Schematic diagram of equivalent pi-line unit

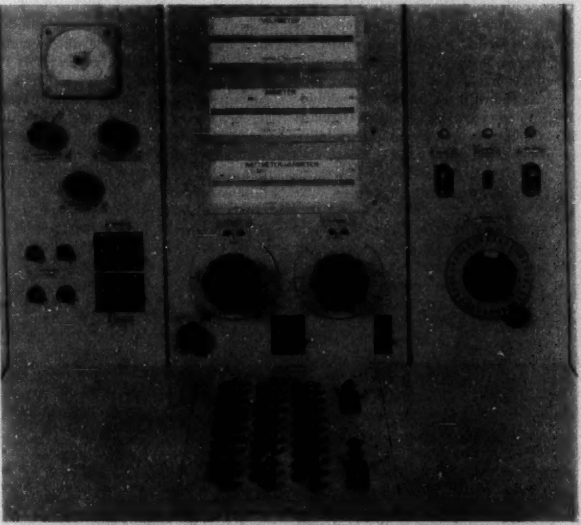

Figure 5. Master-instrument and control panel showing master instruments, scale-selector switches, metering switches, push-button keyboard, and other controls

from the bus. An analyzer unit with jack plug ends on two different busses would read plus power at one end and minus power at the other end, corresponding to the flow of power out of one bus and into the second bus. By having the plus and minus signs in front of the watt and var readings, the recorder readily can add algebraically the power and reactive-power flows over the circuits connecting to each bus to see that they total zero. This may be done conveniently by a third person without delaying the recording process. These checks make it possible to correct errors in reading or recording before conditions on the analyzer have been changed.

Construction and Wiring

Each of the circuit units terminates in plugs in one of the plug and jack cabinets. Because of the large number of circuit units in the analyzer, precautions were taken to minimize the length of interconnecting wires. There is a plug and jack cabinet for every three unit cabinets, with provisions made for interconnecting some of the jacks on each of the cabinets as required by the system connection diagram. The metering bus for each plug and jack cabinet is further subdivided into two sections; only one section is connected to the instrument system at any time. The wiring is carried in a 9-inch high subbase of the analyzer, and all wires are spaced on 1/2-inch centers and away from the steel to minimize the stray effects. This construction permits the complete wiring and testing of the equipment in the factory. The analyzer is built and shipped in sections comprising several cabinets, and relatively few interconnections are required at installation.

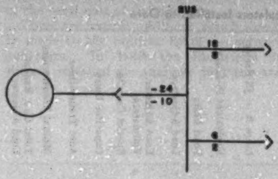

Figure 6. Example of method of representing polarity of watts and vars on a power-flow diagram

Summary

This type of a-c network analyzer with its low volt-ampere base has proved to be of reliable design over a number of years of actual operating experience. The improved analyzer described in this paper incorporates many new features, including direct-reading master instruments, a fuller complement of generator instruments, push-button selection for meter readings, and complete factory assembly and testing. These features should further increase the usefulness of this tool in power-system design.

Discussion

R. B. Squires (Westinghouse Electric Corporation, East Pittsburgh, Pa.): The author's paper is valuable primarily because it gives definite examples of how a large power system can benefit through the use of a network calculator or analyzer. Savings in system design such as is given in the paper have demonstrated the value of the network calculator to an increasing number of utility groups. This has resulted in the installation of a number of calculators throughout the country.

The increase in facilities has been especially rapid since the end of the war. Six network calculators or analyzers have been installed in the last three years, an increase of about 30 per cent over the total prewar figure.

Although the peak has probably passed, the average use of each installation continues at a higher level than before the war, demonstrating that the use expands as more companies have easy access to these devices.

Table I of the discussion has been prepared to summarize the various installations and show their essential features. There is a possibility that on some of the calculators additional facilities have been installed with which we are not familiar.

The network calculators are listed in Table I in the order of their original installation. For example, the second installation was at Westinghouse in East Pittsburgh in 1929. This was reinstalled at Purdue University, with some additions, in 1942. The present Westinghouse calculator dates from that year.

The power supply frequency is usually between 400 and 500 cycles, depending on the design of the manufacturer. For instance, the unit described in this paper uses 480 cycles; the units with which the writer is most familiar use 440 cycles.

The remaining columns show the number of units of each type, such as generators, instruments per generator, load adjusters, load adjuster voltmeters, and how the circuits are selected and metered.

The units listed as pi-line circuits also can be used as regular lines in all cases. The capacitor units listed are those in addition to the capacitors used with the pi-lines. The latter are equal in number to twice the pi-lines, but are not listed in the table.

As can be seen from the table, the majority of the features presented as new in this paper have been incorporated in all calculators manufactured during the past several years. The owners of the more modern equipments appreciate from experience the value of these features.

The network analyzer described in this paper represents an interesting adaptation of up-to-date features, (such as direct reading master instruments, more generator instruments, push button metering, and load adjusting voltmeters) to their high impedance level design. It has been the experience of the writer over the past several years that these features have been great time savers and conveniences on all the modern network calculators. The Bureau of Reclamation will no doubt find them of equal and continuing use in the future.

Edward W. Kimbark (Northwestern University, Evanston, Ill.): The network analyzer described in the paper differs from the one built by the same manufacturer in 1937 with respect to several rather minor details. (Incidentally, the date 1938 given in the present paper is not correct. The analyzer was in full operation in Schenectady by June 1937.) The paper would be more valuable to persons familiar with the earlier models of analyzers if it had specifically listed the features of the new model differing from the 1937 model. These features, as nearly as I can gather them from the paper, are the following:

1. Addition of load adjusters (autotransformers) and voltmeters to the load units.

2. Pi-lines.

3. Decentralization of cord and jack panels.

4. Push-button selector switch of adding-machine style and relays for connecting master instruments to the selected network unit.

5. Automatic change of ammeter and wattmeter scales when range-selector switch is moved.

6. Light-colored paint.

7. Addition of current amplifier to the watt-varmeter on each generator unit.

8. New convention on relative signs of watts and vars at the two ends of a circuit element.

Will the authors please correct me if I have omitted any important changes from this list?

Actually features 1 to 6 are not new, having been included previously in analyzers built by another manufacturer. Thus the present paper offers very little that is really new in network analyzer design or operation.

A network analyzer incorporating at least one important novel feature has been designed by Professor E. B. Phillips and is in operation at the University of Kansas. The novel feature is that impedances set up on the analyzer are shifted by a constant angle of $\cos^{-1} 0.85$ from the corresponding impedances of the power system represented. This feature enables reactors of relatively low Q to be used to represent pure reactance, thus making possible the use of small 60-cycle reactors. The use of 60 cycles eliminates the need of a motor-generator set, which is one of the expensive components of conventional network analyzers. (The expense arises not only from the cost of the motor-generator set itself but also from the fact that, because of its noise, the set must be installed in a separate room and conduits must be installed connecting the two rooms.) It is to be hoped that the appropriate AIEE technical committee will prevail upon Professor Phillips to present to the Institute a complete technical description of his new and very carefully worked-out design.

More innovations such as those on the Phillips analyzer are needed to decrease the cost of network analyzers enough so that every power company can afford to have one. However, even with the present costs, power companies cannot afford not to use network analyzers for studying important changes in their systems. The authors perform a valuable service by citing new examples of possible savings in construction costs without sacrifice of reliability. They also present some interesting thoughts on the pros and cons of rapid-reclosing circuit breakers where the utmost reliability is sought.

Eric T. B. Gross (Illinois Institute of Technology, Chicago, Ill.) This paper is a most valuable contribution since it brings us up to date by the description of a modern analyzer, a tool which simplifies greatly most of the work of the power systems engineers.

It is of interest that in this improved a-c network analyzer nearly all the modifications are incorporated which have been developed in recent years by different users of such calculating boards at various locations. At the Illinois Institute of Technology, we have found the recording table (described in reference 6 of the paper) of great advantage since the work is speeded up considerably, possible errors are checked, and the operating engineer is able to visualize quickly how kilowatts and kilovars are distributed in the whole system. This recording table is of the most help in load studies, and I would say that 20 to 25 per cent more work can be done in the same time with the aid of this tool. I understand that similar recording tables now are in use at some other institutions.

F. S. Rothe: The authors wish to thank the discussors of this paper for their remarks. There is general agreement that the improvements in network analyzers as described in the paper will benefit a large number of users through increased efficiency of operation.

There was criticism of the paper because some of the features described were not new. However, we believe it is fair to say that the features described in general represent definite improvements over existing designs. The method described in the paper for reading megawatts and megavars with the correct sign directly on the master instruments is an example of this.

In connection with the novel analyzer of Professor Phillips, Professor Kimbark cites the saving of a motor generator set as

Table II

eliminating an expensive component from the analyzer. We do not find this to be the case for the low volt ampere base analyzer described in the paper, since the cost of the set, including wiring, is but a small fraction of the total cost of the analyzer.

There are several additions which should be made to Mr. Squires' list of a-c network analyzers. In 1948 the Electricité de France installed an analyzer in Paris and there have been references in the literature to a-c network analyzers in Russia. An up-to-date list of analyzers built by the General Electric Company is given in Table II of this discussion.

General Theory, and Experimental Confirmation, of the Moving Coil Fluxmeter

THOMAS JAMES HIGGINS
MEMBER AIEE

GLENN ROBERTSON
STUDENT MEMBER AIEE

THE moving coil fluxmeter is an instrument for the measurement of magnetic flux. Essentially, the mechanism is that of a D'Arsonval galvanometer so designed that the net restoring torque due to the suspension (if used) and the spiral leads to the moving coil is held to a minimum. Usually, the search coil connected to the fluxmeter is of low resistance. The combination of minimum restoring torque and low search-coil resistance results in a preferred operating characteristic: namely, if under certain conditions the flux ϕ linking the N-turn search coil experiences an incremental change $\Delta\phi$, the deflection D of the pointer of the fluxmeter is proportional to the corresponding incremental change $\Delta\lambda$ in the flux linkages λ associated with the search coil.*

The theory of the fluxmeter has been developed in various degrees of completeness by several writers.[1–9] Study of their papers, epitomized in Appendix I, reveals that in the course of formulating a differential equation which approximately characterizes the deflection D, each writer introduces certain simplifying assumptions. For the most part these assumptions are tantamount to discarding, as negligible by comparison with those remaining, certain terms in the general differential equation which accurately characterizes the deflection D. The approximate differential equation stemming from these assumptions, when solved subject to a prescribed simple set of boundary conditions, has the solution $D=\Delta\lambda/C$; or equivalently

$$\Delta\lambda = CD \tag{1}$$

where C is a constant, fixed by the design of the instrument.

If, as is commonly the case in practice, the same flux ϕ links each of the N_{sc} turns of the search coil, $\Delta\lambda=N_{sc}\Delta\phi$. Substituting this expression in equation 1 and solving for $\Delta\phi$ gives

$$\Delta\phi = CD/N_{sc} \tag{2}$$

One or the other of equations 1 or 2 is the equation implied by the information printed on the scale of a commercial fluxmeter or cited in accounts of the fluxmeter contained in various reference sources: textbooks on electrical measurements or on principles of electrical engineering, handbooks of electrical engineering, instruction manuals for fluxmeters, and elsewhere. In practice, however, it frequently occurs that the actual circuit conditions are such that the terms discarded in formulating the approximate differential equation of which equation 1 is the solution are not negligible. In consequence, calculation by equations 1 or 2 is not valid; depending on the conditions at hand, the calculated values will be either smaller or larger than the actual existing values. Yet accounts of the fluxmeter to be found in available reference sources do not cite the restrictions under which equations 1 and 2 are valid (except that some instruction manuals specify the maximum allowable value of search-coil resistance, a bit of information that often goes unheeded); nor, more generally, do these reference sources discuss how a fluxmeter can be used for accurate measurement under any set of circuit conditions that are likely to occur in practice.

Now, if the general equation relating $\Delta\lambda$ to D were known, analysis of this equation would enable:

1. Determination of the correct use of the fluxmeter under any set of circuit conditions that occur in practice.
2. Establishment of various approximate equations especially convenient for calculation in those situations that most often arise in practice and of the corresponding restrictions limiting use of these approximate equations.
3. Estimate of the error to be expected from use of a given approximate equation.
4. Ascertainment of other factors of interest and value.

Obviously, this information is precisely that which is desired by one who has occasion to make extensive use of the fluxmeter in practice. It is, therefore, the purpose of this paper to provide this desired information for both the unshunted (single-range) and the shunted (multiple-range) fluxmeter.

It happens that the study of each of these two types of fluxmeter falls naturally into three parts:

1. Derivation of the general equation relating $\Delta\lambda$ to D.
2. Deduction from this equation of useful approximate equations, of the corresponding restrictions limiting their use, and of the approximate magnitude of inherent error.
3. Advance of experimental data confirming the correctness of this theory.

---

* This is actually the case, although the information printed on the scale of a commercial fluxmeter usually results in the inexperienced user inferring that deflection is proportional to the change in flux $\Delta\phi$. Again, some textbook accounts of the fluxmeter state, incorrectly, that deflection is proportional to change in flux. Note, however, equation 16. This confusion stems primarily from the fact that, in the sources mentioned, discussion is based on a 1-turn search coil, for which $\Delta\phi$ is numerically equal to $\Delta\lambda$.

Paper 49-168, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer General Meeting, Swampscott, Mass., June 20–24, 1949. Manuscript submitted January 14, 1949; made available for printing May 6, 1949.

THOMAS JAMES HIGGINS is Professor of Electrical Engineering, University of Wisconsin, Madison, Wis. GLENN ROBERTSON is an instructor at Illinois Institute of Technology, Chicago, Ill.

This paper is based upon a thesis supervised by Professor Higgins and submitted by Mr. Robertson to the faculty of Illinois Institute of Technology in January, 1949, in partial fulfillment of the requirements for the degree of Master of Science in Electrical Engineering.

Derivation of the General Equation for the Unshunted Fluxmeter

In the circuit of Figure 1 let e_{sc} be the (instantaneous) voltage generated in the search coil, e_f the voltage generated in the moving coil of the fluxmeter, i the circuit current, R the total resistance, and L the total inductance of the circuit. Then, by Kirchhoff's voltage law

$$e_{sc}=iR+Ldi/dt-e_f \qquad (3)$$

Inasmuch as the fluxmeter is a D'Arsonval galvanometer (with particularly chosen design parameters) its moving coil rotates in a radial magnetic field. Let B be the magnitude of the radial flux density, h and b the vertical height and horizontal breadth of the rectangular moving coil of area $A=hb$ and of N turns, θ the (instantaneous) angular position of the plane of the coil measured from a conveniently chosen reference position $\theta=0$, $w=d\theta/dt$ the angular velocity of the coil, and $v=bw/2$ the linear velocity of the vertical side of the coil angularly located at θ (the other vertical side is located at $\theta+\pi$). Then the voltage generated in one turn of this vertical side of the fluxmeter coil is $-Bhv=-Bhbw/2=-(BA/2)(d\theta/dt)$; whence the voltage generated in the coil is $e_f=-BAN(d\theta/dt)=-Gd\theta/dt$, where $G=BAN$ is a design constant commonly termed the "winding area."

The voltage generated in the search coil is $e_{sc}=d\lambda/dt$, where λ is the negative of the instantaneous flux linkages associated with the search coil.

Substituting for e_{sc} and e_f in equation 3 yields

$$d\lambda/dt=iR+Ldi/dt+Gd\theta/dt \qquad (4)$$

The electrodynamic force acting on a vertical side of one turn of the fluxmeter coil is Bhi; whence the total electrodynamic torque t_e acting to increase θ is $t_e=(Bhi)(bN)=Gi$. The torques acting to prevent increase of θ are: the inertia torque $t_i=Jd^2\theta/dt^2$, the air friction torque $t_f=k_fd\theta/dt$, the electromagnetic checking torque due to eddy currents induced in the metal frame (if any) on which the coil is wound, $t_c=k_cd\theta/dt$, and the restoring torque $t_r=U\theta$, which expression indicates that the reference position $\theta=0$ of the plane of the coil has been chosen to coincide with the position of zero restoring torque—a choice which imposes no limitation on the generality of treatment, yet simplifies the subsequent analysis. Herein, J is the polar moment of inertia of the coil about its vertical axis; k_f and k_c are damping constants (that in moving-coil instruments the friction and electromagnetic checking torques are essentially proportional to the angular velocity of the moving coil has been verified by numerous experiments.[10]); U is the sum of the torsion constant of the suspension if used and the effective spring constant of the spiral or other type of leads to the moving coil.

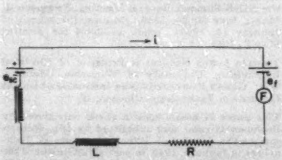

Figure 1. Circuit of unshunted fluxmeter

Equating driving torque to the sum of the opposing torques yields the general differential equation characterizing the mechanical motion of the fluxmeter coil, namely

$$Gi=Jd^2\theta/dt^2+Kd\theta/dt+U\theta \qquad (5)$$

where $K=(k_f+k_c)$.

Solving equation 5 for i, substituting the resulting expression in the term iR of equation 4, and collecting like terms gives

$$d\lambda/dt=(JR/G)d^2\theta/dt^2+[(RK/G)+G]d\theta/dt+Ldi/dt+(UR/G)\theta \qquad (6)$$

Integrating each side of equation 6 between $t=t_1$ and $t=t_2$, where t_1 and t_2 are arbitrary except for the condition $t_2>t_1\geq 0$, yields

$$[\lambda]_{t_1}^{t_2}=(JR/G)[d\theta/dt]_{t_1}^{t_2}+[(RK/G)+G][\theta]_{t_1}^{t_2}+L[i]_{t_1}^{t_2}+(UR/G)\int_{t_1}^{t_2}\theta\,dt \qquad (7)$$

Designating the values of λ, i, θ, and $w=d\theta/dt$ at $t=t_1$ and $t=t_2$ by corresponding subscripts and evaluating equation 7 yields

$$\lambda_2-\lambda_1=(JR/G)(w_2-w_1)+[(RK/G)+G](\theta_2-\theta_1)+L(i_2-i_1)+(UR/G)\int_{t_1}^{t_2}\theta\,dt \qquad (8)$$

Equation 8 is the desired general equation relating change in flux linkages associated with the search coil to the corresponding change in coil position.

Approximations for the Conditions Commonly Encountered in Practice

At $t_1=0$, with the fluxmeter coil at rest ($w_1=0$) at $\theta=\theta_1$, and with zero current ($i_1=0$) through it, let a quick change in the flux linkages associated with the search coil be initiated. The driving torque stemming from the generated current sets the coil in motion. Let $t_2=T$ be the time at which it acquires maximum angular displacement. At this instant $\theta=\theta_2$, $w_2=0$, and $i=i_2$. For the stated boundary conditions, equation 8 reduces to

$$\lambda_2-\lambda_1=[(RK/G)+G](\theta_2-\theta_1)+Li_2+(UR/G)\int_0^T\theta\,dt \qquad (9)$$

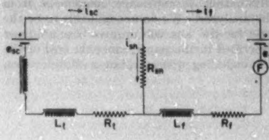

Figure 2. Circuit of shunted fluxmeter

It is commonly the case, in practice, that L is small in comparison with R; that is, the circuit is substantially noninductive.* In such case the circuit current is substantially in phase with the net generated voltage in the circuit. Now the term "quick" implies that the total change in flux linkages has been completed before maximum displacement is attained. If so, at $t=T$ the flux through the search coil is not changing, whence the generated voltage in the search coil is zero. Again, at $t=T$ the fluxmeter coil is stationary ($w_2=0$); whence the generated voltage in the coil is zero, and, as the circuit current is substantially in phase with the net generated voltage, $i_2\cong 0$. Accordingly, for $R>>L$ equation 9 reduces to

$$\lambda_2-\lambda_1=[(RK/G)+G](\theta_2-\theta_1)+(UR/G)\int_0^T\theta\,dt \qquad (10)$$

Thus, unless L is commensurate with R—a case usually encountered in practice only when heavy iron-cored inductors are in series with the fluxmeter—the magnitude of a quick change in flux linkages associated with the search coil is to be calculated, in general, from equation 10. It is to be noted that the restriction to a quick change in flux linkages imposes no essential limitation, for, as discussed below, it is only quick changes that actually are utilized in practice.

Evaluation of the Integral Term in Equation 10

The integral in equation 10 cannot be evaluated explicitly, for θ is an unknown function of t. However, an upper limit to its actual value is established easily by use of a well-known equality in the elementary calculus

$$\left|\int_a^b f(x)dx\right|\leqq\int_a^b|f(x)|dx\leqq|f_m(x)|(b-a) \qquad (11)$$

---

* For detailed discussion of the essential meaning and implications of this statement, see Appendix II.

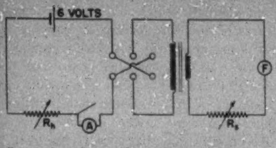

Figure 3. Circuit for studying variation of deflection with circuit resistance

(R_f and R_{sc}) in series with R_s is not shown

wherein $b>a$, and $|f_m(x)|$ designates the maximum magnitude of $f(x)$ in the interval $a \leqq x \leqq b$. Accordingly, it follows from equation 11 that

$$(UR/G)\left|\int_0^T \theta\, dt\right| \leqq (UR/G)T|\theta_m| \tag{12}$$

wherein $|\theta_m|$ designates the maximum magnitude of θ over the time interval $0 \leqq t \leqq T$.

Obviously, $|\theta_m| \geq |\theta_2-\theta_1|$. Usually a fluxmeter is so adjusted and so used in practice that $\theta_1=0$. In this case, $|\theta_m| \equiv |\theta_2|$.

The Case When Both $R>>L$ and $[(RK/G)+G]>>URT/G$

The magnitude of the first term of the right-hand member of equation 10 is $[(RK/G)+G]|\theta_2-\theta_1|$. The magnitude of the second term is, by equation 12, less than or equal to $(URT/G)|\theta_m|$. Accordingly, it follows that if

$$[(RK/G)+G]|\theta_2-\theta_1| >> (URT/G)|\theta_m| \tag{13}$$

equation 10 is well approximated by

$$\lambda_2-\lambda_1 = [(RK/G)+G](\theta_2-\theta_1) \tag{14}$$

Now, it is to be noted that the right-hand side of equation 13 is directly proportional to R, whereas the left-hand side is positively biased by the constant term G. Accordingly, it follows: that for R sufficiently near zero, the right-hand side is very small by comparison with the left-hand side; that as R increases from zero, the right-hand side increases faster than does the left-hand side, thus weakening the inequality; and that possibly (the actual variation depends on the relative values of the other parameters) for sufficiently large R, the two sides become commensurate and the inequality no longer holds.

Accordingly, whether or not this last possibility occurs, there is a range of R for which equation 13 holds. Further, it follows from equation 13 that the upper limit of this range increases as G increases in magnitude and U decreases in magnitude. Now the gain through increasing G, say through using more turns on the fluxmeter coil, tends to be offset by the increased value of T resulting from the more sluggish action of the moving coil because of the increased moment of inertia J. On the other hand, decreasing U also tends to decrease T because of decrease in the restoring torque opposing motion, and decrease of T also tends to extend the maximum value of R for which equation 13 is applicable.

Now, equation 14 is a preferred operating characteristic for a commercial fluxmeter. For if a given fluxmeter is always used with search coils having a specified resistance, the circuit resistance R is substantially constant, and it follows from equation 14 that $(\lambda_2-\lambda_1)$ is of constant proportionality to $(\theta_2-\theta_1)$; whence the scale of the fluxmeter can be calibrated directly in terms of $(\lambda_2-\lambda_1)$. To attain this desired operating characteristic, a commercial fluxmeter is so designed that the moving coil is made as light as is feasible, the winding area as large as is feasible, and the restoring torque is reduced to a minimum. Then G, U, and T are of such magnitudes that the maximum value of R for which equation 13 holds is several times greater than the least value to which R can actually be reduced when using the instrument, namely, R equal to the internal resistance of the fluxmeter. Inasmuch as the bracketed term in equation 14 is positive, it follows that

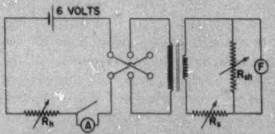

Figure 4. Circuit for studying variation of deflection with shunting resistance

R_f and R_{sc} are not shown

$$|\lambda_2-\lambda_1| = [(RK/G)+G]|\theta_2-\theta_1| \tag{15}$$

The bracketed term in equation 15 is a constant, of specific value determined by the pertinent values of R, K, and G. Thus, it is convenient to write

$$\Delta\lambda = C'D \tag{16}$$

wherein: $\Delta\lambda = |\lambda_2-\lambda_1|$ is the magnitude of the change in flux linkages; $D = |\theta_2-\theta_1|$ is the magnitude of the angular deflection of the moving coil, expressed in scale divisions of angular deflection of the fluxmeter pointer; and

$$C' - [(RK/G)+G] \tag{17}$$

flux linkages/scale division of pointer deflection, is the "working constant" of the instrument.

Accordingly, it follows from equations 16 and 17 that a fluxmeter can be employed in a circuit containing arbitrary total resistance R, and that the change in flux linkages $\Delta\lambda$ associated with the search coil can be calculated with accuracy from equation 16, provided that the corresponding value of C' is known or can be determined, that the specified boundary conditions $w_1=w_2=i_1=0$ are observed, and that the restrictions $R>>L$ and $[(RK/G)+G]D>>(URT/G)|\theta_m|$ are satisfied. Now, as mentioned above, the fluxmeter is usually so adjusted and so used that $\theta_1=0$, whence $|\theta_m| \equiv |\theta_2| \equiv D$. If so, the latter restriction reduces to $[(RK/G)+G]>>(URT/G)$.

Determination of Flux

If $\Delta\lambda$ is written as $\Delta\lambda = N\Delta\phi$ where $\Delta\phi$ is the change in a flux ϕ linking each of the N_{sc} turns of a search coil, equation 16 can be written in the form $\Delta\phi = C'D/N_{sc}$. (This equation implies not only that the same flux ϕ links each of the N_{sc} turns but, further, that the diameter of the wire comprising the search coil is negligible by comparison with the diameter of the cross section of the search coil; whence essentially no flux passes through the wire of the coil. Though these conditions commonly are satisfied in a well-designed search coil, they often are not satisfied if a search coil is constructed by one lacking knowledge of the principles involved.) Obviously, if the change in flux is produced by reversal of a flux ϕ from ϕ to $-\phi$, then $\Delta\phi = 2\phi$, whence $\phi = C'D/2N_{sc}$. Again, if the flux is changed from 0 to ϕ, or from ϕ to zero, then $\Delta\phi = \phi$, whence $\phi = C'D/N_{sc}$.

The Permissible Value of R

It obviously is desirable, for facility of general use, that the scale of a fluxmeter be calibrated directly in terms of the desired quantity $\Delta\lambda$. Inspection of equations 16 and 17 indicates that this can be done, providing R is held constant at

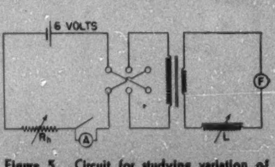

Figure 5. Circuit for studying variation of deflection with circuit inductance

(R_f+R_{sc}) is not shown

some convenient fixed value, say R_m. If R is not constant, calibration still can be essentially accomplished, provided R is allowed to vary only within limits such that $[(RK/G)+G] \cong [(R_m K/G)+G]$. As, in practice, the total resistances of different circuits tend to vary because of differences in the resistances of the leads and search coils utilized, fluxmeters are designed on this latter basis.

Thus, as purchased, the fluxmeter is direct reading for $\Delta\lambda$ and, thus, for $N_{sc}\Delta\phi$, providing it is used in a circuit where R is as specified by the manufacturer. (Usually, this specification is stated in the cover or on the scale of the instrument.) Thus, in Rawson fluxmeters the manufacturer specifies that the resistance of the search coil and associated leads shall not be greater than one ohm. This implies a permissible variation in R over the range $R_f \leqq R \leqq (R_f+1)$, where R_f is the internal resistance of the fluxmeter. Similarly, the early model of Sensitive Research Instrument fluxmeter has a value of R_f of about the same magnitude as that of the Rawson instrument, and the same restriction is stated.

Obviously, then, if R differs from the value R_m for which the scale is calibrated, the user must determine the appropriate value of C', for example, from a calibration curve prepared as discussed in the following section. This restriction on the permissible value of R if the fluxmeter is to be direct reading is an important point in the correct use of a fluxmeter; it is not emphasized or clearly stated in most textbook discussions of the instrument, and is frequently violated in practice if the user is without knowledge of the restriction. Commonly, this violation occurs through use of search coils comprised of many turns of fine wire, and thus of high resistance.

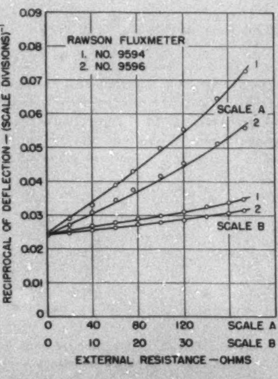

Figure 6. D^{-1} **versus** R_{ex}**: Rawson fluxmeters**

Determination of C'

For $R=R_m$, equation 17 can be written in the form

$$\Delta\lambda = CD \tag{18}$$

where

$$C=[(R_m K/G)+G] \tag{19}$$

Commonly, fluxmeters are designed so that, as received new from the manufacturer, the value of C is

$$\begin{aligned} C &= 10^4 \text{ maxwell-turns/scale division} \\ &\quad \text{(centimeter-gram-second units)} \\ &= 10^{-4} \text{ weber-turns/scale division} \\ &\quad \text{(meter-kilogram-second units)} \end{aligned} \tag{20}$$

Manufacturers print this value of C (usually in centimeter-gram-second units) on the scale of the instrument. However, it commonly happens that with use, or through repair, unless done by the manufacturer, the characteristics of the fluxmeter change somewhat, thus necessitating redetermination of C. Accordingly, when using a fluxmeter it is wise to ascertain whether or not such a redetermined value is to be used; if so, it is commonly to be found recorded in the cover of the instrument.

Occasionally a fluxmeter must be used in a circuit where R is appreciably larger than R_m. For such use it is convenient to have available a calibration curve of C' versus R or R_{ex}. The co-ordinates for such a curve can be obtained in several ways. Thus, for various values of R or R_{ex} the deflections corresponding to a known fixed change in flux linkages $\Delta\lambda$ can be noted and the values of C' calculated from equation 17. The fixed value of flux linkages can be ascertained by initial measurement with $R=R_m$, whence $C'=C$, and $\Delta\lambda$ can be calculated from equation 18; or else a fixed known value can be obtained by reversing a known current passed through a standard mutual inductor or a standard solenoid; or still other artifices can be employed. Again, the values of (K/G) and G can be determined experimentally as discussed in following paragraphs, and values of C', corresponding to various assumed values of R, can be calculated from equation 17.

Extending the Range of a Fluxmeter

The possibility of easy determination of C' enables use of a fluxmeter in a circuit where the value of R is substantially greater than R_m: for example, in a circuit where the search coil, wound of many turns of fine wire for use in mapping a weak magnetic field, is of high resistance. In this case, it follows from equations 17 and 19 that $C'>C$. If so, it follows from equation 16 that a greater change in flux linkages $\Delta\lambda$ is required to produce a given deflection D, now that $C'>C$ is the working constant of the instrument. In turn, this analysis suggests that the range of a fluxmeter can be extended by inserting resistance in series with the fluxmeter. However, this method of extending the range of a fluxmeter is less preferable than that of shunting the fluxmeter coil with a low resistance, for, as is shown below, shunting a fluxmeter, rather than inserting series resistance, enables a greater deflection for the same change in flux linkages, and hence provides greater sensitivity of measurement. In consequence, commercial multiple-range fluxmeters are multiranged by use of shunts.

Incorrect Use of Equations 16 and 18

In conclusion, it is to be noted that use of equations 16 and 18 is subject to the restrictions: $w_2=w_1=\dot{i}_1=0$, $R>>L$, $[(RK/G)+G]|\theta_2-\theta_1|>>|\theta_m|URT/G$. If an of these conditions are substantially departed from, correspondingly modified equations must be used. As a particular example, a student inexperienced in the use of a fluxmeter, having obtained a deflection by reversal of a flux ϕ, and being desirous of obtaining a check through re-reversing the flux to its original value and direction, often does so while the pointer is returning towards its initial position with appreciable velocity

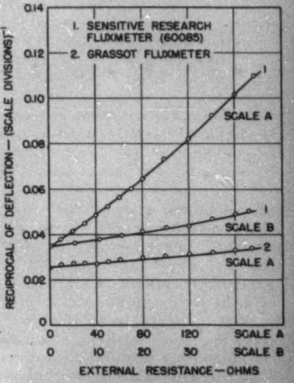

Figure 7. D^{-1} **versus** R_{ex}**: Grassot and Sensitive Research Instrument fluxmeters**

w. At the instant t_1 of re-reversal, however, $w_1>0$; whence it follows from equation 8 that, because of the resulting smaller values of $(JR/G)(w_2-w_1)$ a given change in flux linkages $(\lambda_2-\lambda_1)$ results in a greater value of $(\theta_2-\theta_1)$, and hence a greater pointer deflection D, than would have resulted if w_1 were equal to zero. In consequence, if equation 16 or 18 is, incorrectly, used to calculate $\Delta\lambda$, the larger value of D results in a calculated value of $\Delta\lambda$ greater than the actual value. Obviously, the magnitude of error increases as w_1 increases. In consequence, if through damage and poor repair a fluxmeter coil tends to return rather rapidly towards its initial position, a substantial error easily can result if the fluxmeter is so used.

Derivation of the General Equation for the Shunted Fluxmeter

In the circuit of Figure 2 let $e_{sc}=d\lambda/dt$ be the voltage generated in the search coil, $e_f=-Gd\theta/dt$ the voltage generated in the moving coil of the fluxmeter, i_{sc} the current through the search coil, i_{sh} the current through the shunt, i_f the current through the fluxmeter, L_t and $R_t=(R_{sc}+R_s)$ the total inductance and total resistance of the branch containing the search coil, R_{sh} the resistance, including leads of the shunt, and L_f and R_f the total inductance and total resistance of the branch containing the fluxmeter coil.

Applying Kirchhoff's voltage law to the right-hand loop of Figure 2 yields

$$d\lambda/dt=(i_{sh}+i_f)R_t+L_td(i_{sh}+i_f)/dt+i_{sh}R_{sh} \quad (21)$$

Applying Kirchhoff's voltage law around the outside of the circuit of Figure 2 yields

$$d\lambda/dt=(i_{sh}+i_f)R_t+L_td(i_{sh}+i_f)/dt+i_fR_f+L_f(di_f/dt)+Gd\theta/dt \quad (22)$$

By analogy with equation 5, the differential equation characterizing the mechanical motion of the fluxmeter coil is

$$Gi_f=Jd^2\theta/dt^2+Kd\theta/dt+U\theta \quad (23)$$

Subtracting equation 21 from equation 22 and solving for i_{sh} yields

$$i_{sh}=R_{sh}^{-1}[i_fR_f+L_fdi_f/dt+Gd\theta/dt] \quad (24)$$

Solving equation 23 for i_f and substituting in equation 24 yields

$$i_{sh}=R_{sh}^{-1}G^{-1}[R_fJd^2\theta/dt^2+R_fKd\theta/dt+R_fU\theta]+R_{sh}^{-1}L_fdi_f/dt+R_{sh}^{-1}Gd\theta/dt \quad (25)$$

Integrating equation 21 between t_1 and t_2 gives

$$\int_{t_1}^{t_2}d\lambda=(R_t+R_{sh})\int_{t_1}^{t_2}i_{sh}dt+R_t\times\int_{t_1}^{t_2}i_fdt+L_t[i_{sh}+i_f]_{t_1}^{t_2} \quad (26)$$

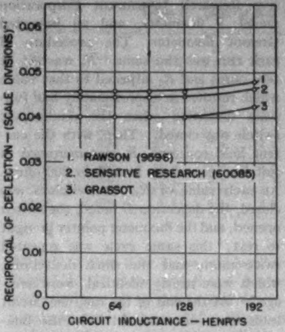

Figure 8. D^{-1} versus circuit inductance L

Substituting from equations 23 and 25 in equation 26 as indicated, performing the indicated integration, and collecting coefficients of like terms yields

$$\lambda_2-\lambda_1=[R_t+R_f(1+R_tR_{sh}^{-1})]JG^{-1}(w_2-w_1)+\{[R_t+R_f(1+R_tR_{sh}^{-1})]KG^{-1}+(1+R_tR_{sh}^{-1})G\}(\theta_2-\theta_1)+(1+R_tR_{sh}^{-1})L_f(i_{f2}-i_{f1})+L_t(i_{sh2}+i_{f2}-i_{sh1}-i_{f1})+[R_t+R_f(1+R_tR_{sh}^{-1})]\times UG^{-1}\int_{t_1}^{t_2}\theta dt \quad (27)$$

Equation 27 can be recast in a form more convenient to analyze; namely

$$\lambda_2-\lambda_1=(R_p+R_f)R_tR_p^{-1}JG^{-1}(w_2-w_1)+[(R_p+R_f)KG^{-1}+G]R_tR_p^{-1}(\theta_2-\theta_1)+R_tR_p^{-1}L_f(i_{f2}-i_{f1})+L_t(i_{sh2}+i_{f2}-i_{sh1}-i_{f1})+(R_p+R_f)R_tR_p^{-1}UG^{-1}\times\int_{t_2}^{t_1}\theta dt \quad (28)$$

where $R_p=R_tR_{sh}/(R_t+R_{sh})$.

Equation 28 is the desired general equation relating change in flux linkages associated with the search coil to the corresponding change in coil position.

The General Equation for the Conditions Usually Encountered in Practice

At $t_1=0$, with the fluxmeter coil at rest $(w_1=0)$ at $\theta=\theta_1$ and with zero current $(i_1=0)$ through it, let a quick change in the flux linkages associated with the search coil be initiated. Let $t_2=T$ be the time at which the fluxmeter pointer attains maximum deflection. At this instant $\theta=\theta_2$, $w_2=0$ and $i=i_2$.

Under these conditions equation 28 yields

$$\lambda_2-\lambda_1=[(R_p+R_f)KG^{-1}+G]R_tR_p^{-1}(\theta_2-\theta_1)+[R_tR_p^{-1}L_fi_{f2}+L_t(i_{sh2}+i_{f2})]+(R_p+R_f)R_tR_p^{-1}UG^{-1}\int_0^T\theta dt \quad (29)$$

As discussed previously, it is commonly true in practice that L_t and L_f are small against the corresponding values of R_t and R_f; whence, as before, $i_{sh2}=i_{f2}\cong 0$. In such case the second term of the right-hand member of equation 29 vanishes. Again, in fashion analogous to the evaluation of the integral term of equation 10, it is to be deduced that the magnitude of the integral term is small by comparison with the magnitude of the first term for a range of (R_p+R_f) such that

$$[(R_p+R_f)KG^{-1}+G]|\theta_2-\theta_1|>>(R_p+R_f)UTG^{-1}|\theta_m| \quad (30)$$

This inequality is the same as the inequality of equation 13, except that R now is replaced by (R_p+R_f). Accordingly, the analysis and remarks developed previously for the unshunted fluxmeter are applicable in obvious fashion to the shunted fluxmeter under discussion here.

In particular, it follows that there is a range of (R_p+R_f) for which the inequality of equation 30 is valid, and that over this range equation 29 is well approximated by

$$\lambda_2-\lambda_1=[(R_p+R_f)KG^{-1}+G]R_tR_p^{-1}(\theta_2-\theta_1) \quad (31)$$

subject to the stated boundary conditions and the restrictions $R_t>>L_t$ and $R_f>>L_f$.

The coefficient of $(\theta_2-\theta_1)$ in equation 31 is a constant of specific value determined by the pertinent values of (R_p+R_f), R_t, K, and G. Thus, again it is convenient to write equation 31 in the form

$$\Delta\lambda=C'D \quad (32)$$

where now

$$C'=[(R_p+R_f)KG^{-1}+G]R_tR_p^{-1} \quad (33)$$

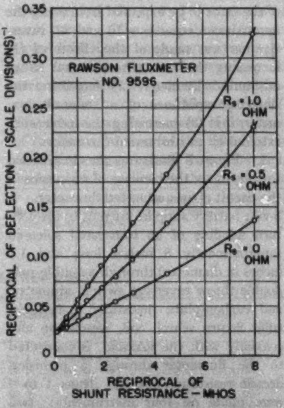

Figure 9. D^{-1} versus R_{sh}^{-1}: Rawson fluxmeter

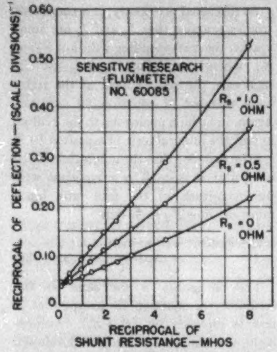

Figure 10. D^{-1} versus R_{sh}^{-1}: Sensitive Research Instrument fluxmeter

Thus, for a given fluxmeter in a given circuit, the coefficient C' in equation 32 is fixed in value. Hence, providing the same precautions are observed as discussed at length for the unshunted fluxmeter, the scale of the instrument can be calibrated in terms of the changes in flux linkages associated with the search coil $\Delta\lambda$. Moreover, as the value of C' depends on the assigned value of $R_p = R_{sh}R_t/(R_{sh}+R_t)$, multiple-range instruments can be obtained by use of several different fixed values of R_{sh}.

Experimental Apparatus and Procedure

To obtain experimental confirmation of the correctness of the theory developed above and to obtain quantitative measure of the error to be expected from using the approximate equations 16 and 32, investigation was made of the effects of (1) increasing the resistance external to an unshunted fluxmeter, (2) decreasing the shunting resistance of a shunted fluxmeter, and (3) increasing the inductance external to an unshunted fluxmeter.

1. Figure 3 illustrates the circuit used to investigate the increase of resistance in the circuit of an unshunted fluxmeter. A 6-volt battery supplies current to the 485-turn winding of an iron-cored solenoid (approximately 8 inches long and 1.5 inches in diameter) through a double-pole double-throw reversing switch, ammeter, and carbon-plate rheostat. A flat circular 8-turn search coil, wound on and coaxially with the solenoid, is connected to the fluxmeter through a precision decade resistance box R_s. Runs 1 to 4 were made on four instruments: two Rawson model 504 fluxmeters, a Sensitive Research Instrument Corporation model *F* fluxmeter, and an imported Grassot fluxmeter. The procedure of each run was the same. R_s was set at zero ohms and R_h adjusted to that value which resulted in approximately half full-scale deflection when the double-pole switch was closed. Then, with the current held constant, R_s was increased in suitable increments from 0 to 200 ohms. At each value of R_s, the switch *S* was closed, the deflection *D* noted, the switch opened, and the fluxmeter pointer brought to rest; this same cycle was repeated twice more, and the three deflections, which were nearly identical, were averaged. At the end of the run, the circuit leads were disconnected from the fluxmeter and connected to a precision 4-decade d-c resistance bridge; the decade resistance box R_s was set in turn to each of the values used during the run, and the total external-circuit resistance R_{ex} was measured. The resistance measured when the decade box is set at zero ohms yields the resistance of the search coil plus circuit leads. Table I comprises a typical set of data—that of run 1.

2. Figure 4 illustrates the circuit used to investigate the effect of decreasing the shunting resistance R_{sh} of a shunted fluxmeter. The circuit derives from that of Figure 3 through the addition of a shunting precision decade resistance box R_{sh}. Runs 5 to 8 were made on four fluxmeters, one of the Rawson instruments noted above being replaced by a General Electric catalog number *32C24764* fluxmeter. Three sets of data were taken for each instrument. For fixed values of R_s equal, in turn, to 0, 0.5, and 1 ohm, R_{sh} was decreased in suitable decrements for infinity (open circuit) to a value yielding a pointer deflection of only several divisions. Data were taken as described above. Finally, the total resistance R_t of the series combination of search coil, resistance box, and leads and the resistance R_{sh} of the shunting resistance box and its leads, were accurately measured with the resistance bridge. Table II comprises a typical set of data—that of Run 5.

3. Figure 5 illustrates the circuit used to investigate the effect of increasing the total inductance *L* relative to the total circuit resistance *R* of an unshunted fluxmeter. The circuit is that of Figure 3 with the precision decade resistance box R_s replaced by a variable heavy iron-cored inductor. Runs 9 to 11 were made on the three fluxmeters used in runs 2, 3, and 4. For a fixed circuit resistance of 26 ohms external to the fluxmeter, *L* was increased in suitable increments from zero to the maximum obtainable value. Data were taken as previously described. The utilized values of *L* then were calculated from measured values of 60-cycle impedance and resistance. Table III comprises the data of runs 9 to 11.

Experimental Confirmation of the Theory of the Unshunted Fluxmeter

If C' from equation 17 is substituted in equation 16 and the resulting expression solved for $D^{-1}(\equiv 1/D)$ we obtain

$$D^{-1} = (K/G\Delta\lambda)R + G/\Delta\lambda \qquad (34)$$

Inasmuch as $R = (R_{ex}+R_f)$, equation 34 can be recast in the form

$$D^{-1} = (K/G\Delta\lambda)R_{ex} + (KG^{-1}R_f + G)/\Delta\lambda \qquad (35)$$

In equation 34 let $\Delta\lambda$ be of fixed value and the equation be interpreted as expressing D^{-1} as a function of *R*. Then equation 34 is that of a straight line, where $(K/G\Delta\lambda)$ is the slope and $(G/\Delta\lambda)$ is the ordinate intercept. Obviously, equation 35 can be similarly analyzed.

Accordingly, if for $R >> L$ and a fixed value of $\Delta\lambda$, *D* is observed as a function of *R*, and if, from these data, D^{-1} is plotted as a function of *R* or R_{ex}, it is to be expected that the resulting curve will be a straight line over that range of *R* for which equations 34 and 35 are valid, namely, the range of *R* for which equation 13 holds.

The curves of Figures 6 and 7, plotted from the data of runs 1 to 4, are precisely such curves. It is to be noted that the

curves for the Rawson and Sensitive Research fluxmeters are linear over essentially the same range of external circuit resistance—about 45 ohms—whereas the Grassot fluxmeter is linear up to about 180 ohms. The greater range of linearity of the Grassot fluxmeter is due to the very delicate system of suspension and spiral connections employed by the moving coil. In consequence, the Grassot fluxmeter has a much smaller value of U. In turn, this smaller value of U enables satisfaction of equation 13 over a range of R several times greater than that of the other instruments.

It is to be noted that beyond the range of linearity the curves of Figures 6 and 7 bend upwards, thus indicating that for a given value of R the value of D^{-1} is greater than would have been obtained if the linear law had persisted over these values of R. This also is to be expected, for the linear characteristic is that which stems from equation 10 when the integral term can be neglected. If it cannot be neglected, it follows that for a given change in flux linkages $(\lambda_2-\lambda_1)$ at a given value of R, the first term of the right-hand member of equation 10 and, therefore, the actual value of $(\theta_2-\theta_1)$, must be smaller than it would be if the integral term were absent. Accordingly, the actual value of $D\equiv|\theta_2-\theta_1|$ will be less and, therefore, the actual value of D^{-1} greater than that calculated on the basis of the linear characteristic stemming from neglect of the integral term. This is precisely what the curves of Figures 6 and 7 evidence.

The curves of Figure 8 are plotted from the data of runs 9 to 11, as tabulated in Table III. In these runs R and $\Delta\lambda$ are held constant; D is determined for increasingly large values of L. Figure 8 evidences that, as L increases, D^{-1} increases; equivalently, as L increases, D decreases—which is to be expected, for, in equation 10, the integral term can be neglected—in which case $(\theta_2-\theta_1)$ will be constant for a constant change in flux linkages $(\lambda_2-\lambda_1)$—only if equation 13 is satisfied. In the experimental work, $\theta_1=0$; whence $|\theta_2-\theta_1|=|\theta_2|\equiv|\theta_m|$ and the inequality equation 13 reduces to $[(RK/G)+G]>>URT/G$. As L increases, however, the motion of the moving coil becomes increasingly more sluggish because of the slower rate of increase of the induced current in the circuit and, as was actually found in the experimental work, T increases substantially with L. Thus, the right-hand side of the inequality increases with L, and the left-hand side is constant; the inequality weakens as L increases. Eventually a value of L is reached for which the integral term in equation 10 cannot be neglected. Since this term increases in magnitude relative to the preceding term as L increases, since $(\lambda_2-\lambda_1)$ is constant, and since the coefficient $[(RK/G)+G]$ is constant, it follows that $(\theta_2-\theta_1)$ must decrease as L increases. Thus, $|\theta_2-\theta_1|=D^{-1}$ increases with L—in precise agreement with the curves of Figure 8. As before, the slower increase of D^{-1} manifest for the Grassot fluxmeter stems from its value of U being much smaller than those of the other two fluxmeters.

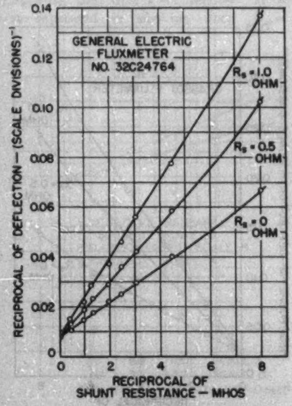

Figure 11. D^{-1} versus R_{sh}^{-1}: General Electric fluxmeter

Obviously, Figure 8 confirms Golding's[6] conjecture that a substantial value of inductance can be inserted in a fluxmeter circuit without appreciable change in the working constant of the fluxmeter.

Experimental Confirmation of the Theory of the Shunted Fluxmeter

If C' from equation 33 is substituted in equation 32, R_p^{-1} replaced by its value $(R_t+R_{sh})/R_tR_{sh}$, and the resulting expression solved for D^{-1}, we obtain

$$D^{-1}=[(1/\Delta\lambda)(R_fKG^{-1}+G)R_t]R_{sh}^{-1}+(1/\Delta\lambda)[(R_t+R_f)KG^{-1}+G] \quad (34)$$

In equation 34 let $\Delta\lambda$ and R_t be of fixed value and let the equation be interpreted as expressing D^{-1} as a function of R_{sh}^{-1}. Then equation 34 is that of a straight line where $(1/\Delta\lambda)(R_fKG^{-1}+G)R_t$ is the slope and $(1/\Delta\lambda)[(R_t+R_f)KG^{-1}+G]$ is the ordinate intercept. Accordingly, if for $R_t>>L_t$ and $R_f>>L_f$ and for fixed values of $\Delta\lambda$ and R_t, D is observed as a function of R_{sh}^{-1}, it is to be expected that the resulting curve will be a straight line over the range of R_{sh}^{-1} for which equations 32 and 34 are valid, namely, the range of R_{sh}^{-1} for which equation 30 holds.

The curves* of Figures 9 to 12, plotted from the data of runs 5 to 8, are precisely such curves. The curves bend upwards beyond the linear range, for reason analogous to that discussed previously in accounting for the corresponding phenomenon in the curves of Figures 6 and 7. The increase, as R_s increases, of the slopes of the linear portions of the three curves of a given figure stems from the fact, evidenced in equation 34, that the slope is

40.0	140	36.2	1.06	200	300	27.9	1.38

directly proportional to R_t, increasing with R_t and thus with R_s, since $R_t=(R_s+R_{sc})$. A corresponding increase in the ordinate intercept $(1/\Delta\lambda)[(R_t+R_f)\times KG^{-1}+G]$ actually occurs as R_s increases from 0 to 0.5 to 1 ohm, but because of the relative magnitudes of the parameters in this expression, the increases are too small to be detected on the curves. Accordingly, all three curves appear to have the same ordinate intercept.

Determination of C'

The various excellent agreements between theory and experiment as previously set forth substantiate in general the correctness of the theory developed for the unshunted and the shunted fluxmeters. In particular, it follows that a fluxmeter can be used for accurate measurement in a circuit where the resistance external to the fluxmeter is any arbitrary value within the linear range of the instrument, providing the corresponding value of C' is used in working equation 16 or 32.

For an unshunted fluxmeter it follows from equation 16 that, if $\Delta\lambda$ is of constant value, then $C'D'=CD_C$, or, equivalently

$$(C'/C)=(D')^{-1}/D_C^{-1} \qquad (35)$$

where C' and $(D')^{-1}$ are corresponding values for an arbitrary value of total circuit resistance R, and C and D_C^{-1} are corresponding values for $R=R_m$. R_m and C are stated by the manufacturer; D_C^{-1} and $(D')^{-1}$ can be obtained from a constant $\Delta\lambda$ curve of D^{-1} versus R or a constant $\Delta\lambda$ curve of D^{-1} versus R_{ex}, as in Figures 6 and 7. If, with values so obtained, the corresponding values of C' versus R or R_{ex} are plotted, the resulting calibration curve furnishes ready determination of the working constant C' for any value of R or R_{ex} that can be utilized in practice.

For convenience of use it usually is preferable to plot a calibration curve of C'/C versus $R_{ex}=R-R_f$. The curves of Figure 13 are precisely such curves. These curves are plotted from data typified by that of Table IV for the Grassot fluxmeter. The values therein are calculated, as just outlined, from smoothed data taken from the pertinent curve of Figure 6. For each of the three fluxmeters, $C'=C$ when $R=R_m=R_f$, for the manufacturer's injunction that the external resistance R_{ex} be kept below one ohm implies that the working constant is C when $R_{ex}=0$. Accordingly, a value of C'/C corresponding to a given value of R_{ex} is to be calculated by dividing the corresponding value of D^{-1} by the value of $D^{-1}\equiv D_C^{-1}$ for $R_{ex}=0$.

Figure 14 comprises a calibration curve of C'/C versus R, and is included for use with the material which follows.

The linearity of the curves of Figures 13 and 14 is to be expected, for over the linear range of R, the constant C' is defined by equation 17. This can be written in the form

$$(C'/C)=(K/GC)R+(G/C) \qquad (36)$$

Since $R=R_{ex}+R_f$ equation 36 can be written in the form

$$(C'/C)=(K/GC)R_{ex}+(K/GC)R_f+(G/C) \qquad (37)$$

For the fluxmeters under discussion, $R_m=R_f$. Accordingly, it follows from equation 19 that equation 37 can be written in the form

$$C'/C=(K/GC)R_{ex}+1 \qquad (38)$$

If equation 36 be interpreted as expressing C'/C as a function of R, it is the equation of a straight line of slope K/GC and ordinate intercept G/C. Similarly, equation 38 is that of a straight line of slope K/GC and ordinate intercept one. Accordingly, if, over the linear range of R, experimentally determined values of C'/C be plotted as a function of R or R_{ex}, it is to be expected that the resulting curve will be a straight line—as in Figures 13 and 14.

The values of C for the fluxmeters of Figures 13 and 14 are encompassed in Table V. As purchased new, each fluxmeter had a working constant of $C=10^4$ maxwell-turns. But because of student use, with resulting damage and repair in the school's instrument shop, the present values of C are as tabulated. These values were determined by use of a Cenco Standard Variable Magnetic Inductor. Interestingly, the C of the Grassot instrument, maintained as the laboratory standard, has not changed appreciably since purchase several decades ago. This indicates that if a fluxmeter has been used only by those experienced and careful in use of it, C can be taken as the new value; it is not necessary to make a separate determination of C prior to using the calibration curve of C'/C versus R or R_{ex}.

Determination of the Parameters of a Fluxmeter

As discussed immediately after equation 38, the curves of Figure 14 are straight lines of slope K/GC and ordinate intercept G/C. Accordingly, the values of K/GC and G/C can be scaled from the curves of Figure 14. From these values and the values of C in Table V, K/G, G, and K can be calculated. The corresponding numerical values are tabulated in Table V.

The units of the tabulated values are: R_f in ohms; C and G in maxwell-turns per scale-division; K/G in maxwell-turns per ohm scale-division; K in maxwell-turns^2 per ohm scale-division^2; and U_m in maxwell-turns^2 per ohm second scale-division.^{2}

To determine U we note that equation 10 can be written in the form

$$D^{-1}=(K/G\Delta\lambda)(R_{ex}+R_f)+(G/\Delta\lambda)+(URD^{-1}/G\Delta\lambda)\int^{T}\beta dt \qquad (39)$$

This equation is the over-all characteristic of the curves of Figures 6 and 7. Omission of the integral term yields equation 34, the equation of the linear portion of the curves of Figures 6 and 7, hence also the equation of the straight lines obtained by extending the linear portions. Accordingly, it follows that, for a given

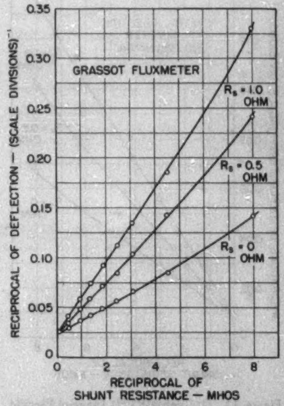

Figure 12. D^{-1} versus R_{sh}^{-1}; Grassot fluxmeter

value of R_{ex}, hence of $(R_{ex}+R_f)$, the integral term is the magnitude of the difference between the actual ordinate of the curve D^{-1} and the ordinate of the linear portion extended d^{-1}. Now as discussed previously, $\left|\int_0^T \theta dt\right| = T\left|(\theta_2-\theta_1)_m\right|$. All experimental data were taken for $\theta_1=0$, whence $\left|(\theta_2-\theta_1)_m\right| = \left|\theta_2\right| \equiv D$. Accordingly for the case at hand, $(D^{-1}-d^{-1}) \equiv (URD^{-1}/G\Delta\lambda)\int_0^T \theta dt \leqq URT/G\Delta\lambda$. In consequence, $(D^{-1}-d^{-1})G\Delta\lambda/RT \leqq U$, or since $\Delta\lambda = CD_C$

$$(D^{-1}-d_1^{-1})GCD_C/RT \leqq U \qquad (40)$$

Equation 40 yields a minimum value of U. Actual observation of θ as a function of t indicates that the two are approximately linearly related over a considerable portion of the deflection. In consequence, the actual value of U is approximately twice the minimum value of equation 40. But although equation 40 thus does not yield the actual value of U, it furnishes information sufficient to ascertain the order of magnitude of U for the fluxmeters of Table V and also the relative sizes of the parameters of the three instruments—all that is desired for the purpose at hand.

Minimum values of U, calculated from equation 40, are tabulated in Table V. The necessary values of the ordinates have been scaled from the curves of Figures 6 and 7 for $R_{ex}=200$. Calculation is typified by that for the Sensitive Research Instrument fluxmeter: $(D^{-1}-d^{-1}) = 1.44\times10^{-2}$, $U_m = [(1.44\times10^{-2})(8.9\times10^{-3})(1.13\times10^4)(28.8)/(211)\times(1)] = 1.97\times10^5$.

It is to be recalled that D_C is the deflection corresponding to $R_{ex}=0$, $R=R_{ex}+R_f$; and that $T=1$ second. If R is expressed in abohms, then $U_m = 1.97\times10^{-4}$ dyne-centimeter per scale division.

The small value of the U_m of the Grassot fluxmeter stems from the previously mentioned very delicate system of suspension and spiral connection employed with the moving coil.

Table V. Parameters of Fluxmeters*

Fluxmeter	R_f	C	K/G	G	K	U_m
Rawson	16.5	1.08×10^4	83.5	8.7×10^3	72.7×10^4	0.57×10^5
Sensitive Research Instrument	11.0	1.13×10^4	107.0	8.9×10^3	95.0×10^4	1.94×10^5
Grassot	100.0	1.00×10^4	16.3	8.4×10^3	13.7×10^4	0.10×10^5

* See text for statement of units of tabulated values.

Misstatements in Textbooks

The fact that some textbooks state, incorrectly, that the deflection of a fluxmeter is proportional to the change in flux, rather than—correctly—to the change in flux linkages, has been mentioned in the introduction. Again, in developing a theory of the fluxmeter, some textbooks assume that the "RI drop" can be neglected. Commonly, this term is considered negligible because the current is small, whence also the RI drop is small. The resulting analysis yields a working constant equivalent to that defined by equation 14 where $R=0$. As evidenced by Figure 14, however, the working constant of the Grassot fluxmeter, for example, would be 0.834×10^4 for $R=0$, as compared with the actual value of 10^4 for $R=R_f=100$ ohms; or, again, that of the Rawson fluxmeter would be 0.838×10^4 for $R=0$, as compared with the actual value of 1.08×10^4 for $R=R_f=16.5$ ohms.

Obviously, it is most desirable that a textbook development of the theory of the fluxmeter should retain the iR term of equation 4, obtain the actual linear-range working constant C' of equation 14, and therefrom stress the significance of maintaining the resistance of the fluxmeter circuit at substantially the manufacturer's value of R if his value of C is to be used as the working constant. As an example of the practical importance of such a discussion, it is to be noted that the working constant $C=10^4$ of the multiple-range fluxmeter manufactured by the Sensitive Research Instrument Corporation is based on using the fluxmeter with a special 15-ohm search coil. If some other search coil of small resistance is used, as may be necessary for a particular measurement, it is imperative that additional series resistance be added to make $R_{ex}=15$ ohms if $C=10^4$ is still to be the working constant. The necessity of adding the additional series resistance is obvious if the dependence of C' on R is known to the user, but otherwise the necessity is not evident.

Summary

1. An inclusive mathematical theory of the operation of the unshunted fluxmeter is developed. Previously published accounts of the theory of the unshunted fluxmeter are analyzed and found to be encompassed as special subcases of the theory developed in this paper.

2. From the general equation of operation a simple approximate equation is deduced which can be utilized for accurate calculation, provided the stated pertinent boundary conditions and restrictions are observed.

3. Experimental data are advanced which confirm the correctness of the general theory and make clear the necessity of observing the stated boundary conditions and restrictions.

4. Analysis and experimental confirmation analogous to that outlined in the three preceding paragraphs is advanced for the shunted fluxmeter.

5. Experiment reveals that a considerable amount of inductance can be inserted in series with a fluxmeter without substantially changing the working constant of the instrument.

6. Experiment indicated that a fluxmeter can be used in a search-coil circuit of arbitrary resistance up to, in general, several times its internal resistance, provided that the corresponding numerical value of the working constant C' is selected from the

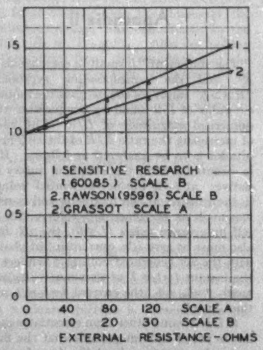

Figure 13. Calibration curves of C' versus external resistance R_{ex}

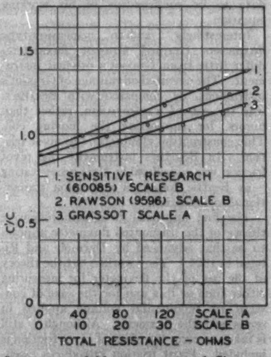

Figure 14. Calibration curves of C' versus total circuit resistance R

calibration curve of C' versus circuit resistance. A combined numerical-experimental procedure for effecting this calibration curve is advanced. This procedure is illustrated by effecting the calibration curves of several fluxmeters.

7. A procedure for determining the mechanical and electrical parameters of a fluxmeter is advanced and illustrated by calculation of the parameters of several different fluxmeters.

8. Several misstatements commonly found in reference sources are mentioned and suggestion advanced as to how to correct these inaccurate statements.

Appendix I

In 1902 Beattie[1] suggested that a pivot-type D'Arsonval galvanometer designed with minimum restoring torque and used in a circuit of low resistance could be employed for determination of the flux in an iron specimen on which a hysteresis loop was being run. Taking R, L, and U as zero enabled Beattie to deduce an equation relating D to Q, the total charge passed through the fluxmeter by the voltage generated in the search coil. From knowledge of Q the change in flux $\Delta\phi$ is then determined as when using a ballistic galvanometer for flux determination. Beattie constructed an instrument, tested it, and found experimental data to be confirmative of his working equation.

Thus, Beattie proposed the instrument now termed the pivot-type fluxmeter, but it is to be noted that he used it as a charge meter—hence his name of quantometer for the instrument. In 1904 Grassot[2] suggested that a suspension-type D'Arsonval galvanometer designed with minimum restoring torque and used in a circuit of low resistance could be used for the direct measurement of flux. Taking R, L, and U as zero yielded a working constant $C'=G$, to be obtained from equation 17 by setting $R=0$. As deflection is directly proportional to change in "flux," Grassot termed the instrument a fluxmeter. Grassot constructed an instrument, tested it, and found experimental data to be confirmative of his working equation.

Interestingly, modern suspension-type fluxmeters (termed Grassot fluxmeters) differ little from Grassot's original instrument. The essential advantage of Grassot's instrument, as compared with Beattie's, was the use of a suspension, rather than pivots, for supporting the moving coil. This construction eliminates the pivot friction. In Beattie's instrument the pivot friction was considerable, thus necessitating —as Beattie found—a correction proportional to deflection.

The first approach to a comprehensive theory of the unshunted fluxmeter appears to be that advanced by Darmois and Ribaud in 1924.[3] They worked out the theory of the use of the fluxmeter for measuring either time or flux and for the case of constant or exponential voltage applied in series with the fluxmeter. Although U still is taken as zero, the effect of pivot friction is included. Pivot friction introduces essentially a Coulomb friction force: that is, the pivot friction torque is a constant F, independent of the angular position of the moving coil. Pivot friction torque was neglected in formulating the theory of this paper as it is negligible in modern fluxmeters. However, it is easily introduced. Thus adding the opposing pivot friction torque F to the right-hand side of equation 5 results in an additional term FR/G in equation 6, an additional term $FR(t_2-t_1)/G$ in equations 7 and 8, and an additional term FRT/G in equations 9 and 10. If in this resulting equation 10, the integral term is taken as zero through assuming $U=0$, we obtain Darmois and Ribaud's working equation. In modern instruments, however, it is the restoring torque and not the pivot torque which results in departure from linear operation—except, of course, in a pivot-type fluxmeter where long continued use or careless handling has resulted in deterioration of the jewels or pivots.

Table VI. Maximum and Final Deflections in Run 9

L Henrys	D_m	D_f

32	25	22
64	26	22
96	27	22
128	26	22
192	25	21

Darmois and Ribaud effect, for certain conditions, the equation for the deflection as a function of time. In so doing they find that if $L>JR^2/4G$, the motion of the moving coil in taking up its final position is a highly damped oscillation. This phenomenon was observed during the experimental work of runs 9, 10, and 11. As indicated by the data in Table VI for the Rawson fluxmeter, for values of L other than $L=0$, the pointer swung up to a maximum deflection, then dropped back several divisions to the final steady-state value. It may be noted that as L increases from 0 to larger values, R being constant, the inequality $L>(JR^2/4G)$ strengthens. Correspondingly, the degree of oscillation increases at first; whence the greater difference between D_m and D_f with increase of L, as tabulated in Table VI. But as L is increased, the effect of the integral term in equation 8, neglected in Darmois and Ribaud's analysis, also increases. The effect of this term is such that at a certain value of L the value of D_m is a maximum and thereafter decreases as L increases—as is manifest in Table VI.

The effect of restoring torque was first considered by Surugue.[4] In 1935 he worked out a theory wherein F, L, and U are taken as zero. The resulting working constant is identical with equation 17. The effect of restoring torque is then introduced through use of an additional semiempirically-determined factor multiplying C'.

In reviewing the theory pertinent to use of the fluxmeter as a device for the integration of current or voltage over a long period of time, Dunn[5] (1939) points out that neglect of the integral term of equation 10 introduces a substantial error in the measured quantity; he names this term the "drift error" because after deflection the pointer drifts back towards zero under the influence of $U\neq 0$, and finds its maximum value to be URT/G—in agreement with the value found in the more comprehensive discussion of this paper. This reference contains statement of experimental methods, different from those used herein, for obtaining the parameters of a fluxmeter.

In 1933 Golding[6,7] advanced theory for both the unshunted and the shunted fluxmeter. In the first instance R, L, F, and U are taken as zero, whence the working constant obtained is $C'=G$, to be obtained from equation 17 by setting $R=0$. Corresponding approximate treatment of the shunted fluxmeter results in a working constant $C'=G(R_{sh}+R_t)/R_{sh}=GR_tR_p{}^{-1}$. This differs from the accurate working constant of equation 33 in that the first term of the latter is missing—a consequence of approximations introduced in effecting the theory. Golding's theory is encompassed in his book,[12] and in a survey paper by Miller.[8]

A more accurate theory of the shunted fluxmeter was worked out by Tagg[9] in 1945, in the course of formulating the general theory of the time–deflection characteristics of moving-coil instruments. Taking F and U as zero yields working constants for the unshunted and shunted fluxmeters which are identical with those of equations 17 and 33.

To conclude, although the following are not concerned with general theory, they encompass information on fluxmeters which is of particular interest.

1. Haworth[13] has described use of a fluxmeter with feedback applied through a phototube which results in counterbalance of the restoring torque, thus eliminating the drift toward zero after attainment of deflection.

2. As evidenced by the curves of Figures 6, 7, 13, and 14, the sensitivity of a moving-coil fluxmeter decreases as circuit resistance increases. In consequence, if the search-coil resistance is high (as may be the case in mapping rapidly-varying weak magnetic fields), the deflection may be too small for accurate measurement. Dicke[14] has described an electronic fluxmeter which possesses among other advantages both zero drift and the possibility of use of search coils of resistance up to 10,000 ohms.

3. The remarks of Salisbury[15] on calibration of moving-coil fluxmeters are of general interest and utility.

Appendix II

The statement "L small in comparison to R" and the corresponding symbolism "$R>>L$" imply, of course, that the numerical value of L is small by comparison with numerical magnitude of L/R. The effect of increasing the ratio L/R of the two magnitudes is to be analyzed as follows. If L is essentially zero, the circuit is purely resistive; at $t=t_2$ the net generated voltage in the search coil and fluxmeter coil is zero; inasmuch as no generated voltage due to self inductance exists ($L\cong 0$), the iR drop also must be zero (the current is "in phase" with the net generated voltage); whence at the instant $t=t_2=T$ of maximum displacement, $\theta=\theta_m=\theta_2$, the current $i=i_2=0$, and thus $Li_2=0$.

If L is a value other than essentially zero, but is yet of such magnitude that the fluxmeter does not overshoot the "steady-state deflection" (defined below), it still is true that, at $t_2=T$, the net generated voltage in the circuit is zero, but it does not now follow that $i_2=0$. For inasmuch as the circuit is not purely resistive, an electromotive force generated by change of current in the self-inductance of the circuit can support an equal i_2R drop at $t=t_2$. All that now can be said is that at $t=t_2$ the combined mechanical and electrical torque is zero. However, it is obviously true that, if L does not differ too much from zero (whence for arbitrary but fixed R, the ratio L/R is still small), it is to be expected that circuit conditions at $t=t_2$ are approximated by those holding for $L=0$, whence i_2 and thus Li_2 are substantially zero.

However, in a well-adjusted fluxmeter, the drift is extremely slow, whence the reading is taken at steady-state deflection. Accordingly, it must be that in such a fluxmeter $i_2=0$. (Otherwise an electromagnetic torque exists and steady-state deflection is not the case) Accordingly, if $t_2=T$ is taken, more generally, as the time of attainment of steady-state deflection, $i_2=0$, and the analysis is yet as given, except now θ_2 is the position of steady-state deflection. This position may or may not be that of maximum deflection for if L is sufficiently large, the fluxmeter will overshoot as evidenced in Table VI and discussed in Appendix I. If it is, $|\theta_2|=|\theta_m|$; if not, $|\theta_2|<|\theta_m|$.

From the practical point of view, the experimental curves of Figure 5 evidence that the self-inductance of the circuit must be considerable before steady-state deflection is influenced; whence it could be deduced directly from experiment that analysis based on neglect in equation 9 not only of Li_2, but of the influence of L on the value of

$$(UR/G)\int_0^T\theta/dt$$

as well, is valid up to very large values of L.

Discussion

Frank Wenner (Consulting Physicist, Washington, D. C.): Obviously the authors have arrived at a very much better understanding of the actions of a fluxmeter (that is, a heavily overdamped galvanometer when used ballistically) than that apparently possessed by most of those who have written on the subject. There are, however, a number of points which might be explained in such a way as to ease the requirements on the part of the reader. One only, and scarcely the most important of these, is selected for discussion here. It is the transition from equation 15 to equation 31.

Keeping in mind equation 15 and applying the principle of the potential divider, it follows from an inspection of Figure 2 (neglecting L_t, L_f) that for the same electromotive force impulse into the fluxmeter the flux-linkage change must be increased by the factor $(R_t + R_{sh})/R_{sh}$. Also on looking at the circuit from the standpoint of the fluxmeter it follows from an inspection of Figure 2 that the resistance $R = R_f + R_{sh}R_t/R_{sh} + R_t$. Consequently when the fluxmeter is shunted, equation 15 takes the form

$$\lambda_2-\lambda_1=[(R_t+R_{sh}/R_{sh})]\{[R_f+R_{sh}R_t/(R_{sh}+R_t)]K/G+G\}(\theta_2-\theta_1)$$

This is equivalent to equation 31 provided the typographical error in the equation defining R_p is taken into account. Thus by using relations well-known to most of those skilled in electrical measurements instead of one of Kirchhoff's laws, not only is a considerable amount of algebra avoided but a clearer picture is presented to the reader.

Morley J. Lush (Rawson Electrical Instrument Company, Cambridge, Mass.): The authors are to be congratulated for finally bringing together, in one equation and discussion, all the error-producing factors which can influence the results when using regular commercial models of the fluxmeter.

Recent experiments by this writer have shown that values of both K and U can be reduced considerably without making the instrument as delicate as the old Grassot type.

It should be noted that the results in the paper were obtained with a circuit giving practically instantaneous changes of flux linkage. If hand-operated search-coils are used, with time intervals up to one-half second, it is not possible to use search-coil resistances as high as those mentioned. Under these conditions, the integral term in equation 10 due to spiral torque is sufficient to cause an error which is variable unless the time interval can be standardized in some way. The Rawson Company has always recommended a search-coil resistance under one ohm whenever possible, practically eliminating all errors, or a maximum value of 10 ohms if corrections can be made.

It is possible to invert equation 15 using the first two terms of a series expansion, and put it into the form

$$S=S_0\left[1-\frac{S_0KR_{sc}}{G}\right]$$

where S is the general sensitivity, and S_0 is the scale calibration sensitivity ($R_{sc}=O$). Both S and S_0 are in divisions per flux linkage. The equation is within one-half of 1 per cent if the second term is less than 5 per cent. To one further degree of approximation

$$S=S_0\left[1-\frac{S_0^2KR_{sc}}{10^9}\right]$$

This form of the equation is interesting because it shows that the variation in calibration constant with search-coil resistance depends upon air damping constant K and the square of the sensitivity. If a deflection sensitivity higher than that of the old Grassot instrument is attempted, the calibration constant becomes very dependent upon the search-coil resistance (unless the air damping can be reduced in some way). This explains why some makers have adopted the practice of requiring all search-coils to be adjusted to a particular value of resistance.

Thomas James Higgins and **Glenn Robertson:** Mr. Lush's equation neatly exhibits the dependence of sensitivity on search coil resistance and very well complements the author's discussion thereof.

With respect to Dr. Wenner's remark that "there are a number of points which might have been explained in such a way as to ease the requirements on the part of the reader" the authors would point out that Dr. Wenner's purported derivation of their equation 31 is invalidated by his remark "neglecting L_t, L_f".

If the authors had chosen to neglect terms *a priori* they could have shortened the over-all analysis of the paper considerably. Rather, it was their stated intention, to carefully and completely consider the influence of all pertinent factors and to establish definitely under what conditions certain approximations could be introduced, that necessitated the approach through Kirchhoff's laws. Thus, it is clearly established in the paper under what conditions terms involving inductances drop out, thus resulting in equation 31. On the other hand, Dr. Wenner merely "neglects L_t, L_f" whence (on the basis of Dr. Wenner's derivation) no specific condition results as to when his resulting equation is valid.

Further, it was not the intention of the authors that their paper would be intelligible merely "to most of those skilled in electrical measurements" but rather to so write that the paper as a whole would be clear to any reader with an ordinary undergraduate training in circuit analysis and electrical measurements. For it is the engineer with only an average training in electrical measurements who commonly falls into error in using a fluxmeter, not the highly-skilled worker in electrical measurements.

A 66-Kv Subtransmission Plan for a Metropolitan Area

K. M. SMITH
MEMBER AIEE

E. L. MICHELSON
MEMBER AIEE

THE planning of the subtransmission system to deliver power from the power supply station to the substation represents a fertile field for the activities of the system planning engineer. Many different possibilities present themselves in any particular system, and there are numerous factors that require consideration before the most desirable plan can be determined. The basic conditions change from time to time, so that it is necessary to review the problem periodically to take into account new developments that affect the economics of the subtransmission system.

In Chicago a new arrangement was adopted recently to provide for the expansion in load which is being experienced. This arrangement utilizes as a subtransmission voltage 66 kv, formerly used only at transmission levels. In this paper the basic reasons for the adoption of the new system are described, and some of the details of the system are discussed from the viewpoint of the system planning engineer. In order to provide a background for this discussion, the history of the Chicago system is reviewed briefly.

History of the Chicago Power System

In the early development of the power system in the city of Chicago, all the generators were located inside the city and relatively close to the load. The subtransmission for the 60-cycle load consisted of lines at the generated voltage (12 kv) direct from the generating station to the distribution substations, and the various generating stations were sometimes interconnected by these same 12-kv lines. The complexity of this arrangement caused difficulties in operation and protection, and led to the separation of the 12-kv system into various subtransmission zones, supplied from major 12-kv switchhouses originally located exclusively at the sites of generation. These zones were then interconnected by a 66-kv transmission system.

Figure 1 shows in detail the connections of one of these generating station switchhouses and a typical arrangement of 12-kv lines and substations. Several substations are combined into a group, which operates independently of other groups. In this manner a highly reliable system has been developed, which is relatively simple to operate and protect.

A further development in the subtransmission arrangement occurred in the late 1920's and early 1930's, when two large distributing stations were constructed along the route of the 66-kv interconnections, midway between generating stations. These distributing stations were supplied by 66/12-kv transformers from the 66-kv transmission system, and served as a source of supply for the subtransmission lines in their vicinities. The length of 12-kv lines required for subtransmission was thereby reduced. The 12-kv switching structures at these stations are similar in size and construction to the switchhouses at generating stations.

The system as it existed previous to the current development under discussion is shown in simplified form in Figure 2. At this time there was a total of 275 12-kv lines supplied from seven switchhouses located on six sites. These lines are usually 3-conductor 500,000-circular-mil underground cable.

With a closely interconnected high capacity system, it is obvious that potentially high fault currents are available. The switchhouses built since 1921 have therefore been of isolated-phase construction. This design is carried through the 66-kv transmission system by the use of single phase transformers and single conductor cable, so that the possibility of a phase-to-phase fault on these elements of the system was practically eliminated. Neutral grounding resistors are used on the 66-kv system and in the 12-kv generating stations to limit the phase-to-ground fault currents, and reactors are installed on the 12-kv lines at the switchhouses to reduce the effect of phase-to-phase faults on the 3-conductor subtransmission cables. As a result of this design, it has been possible to operate the phase-isolated 12-kv switchhouses and 66-kv terminals with circuit breakers rated below the calculated 3-phase fault current. Normal or automatic sectionalization of busses has effected a further reduction of fault current.

Recent Developments

While the design of switchhouse construction and the subtransmission arrangement described have been quite successful and reliable, certain recent developments, as outlined in the following, have stimulated consideration of an alternative plan:

1. In recent years it has been necessary to develop generating sites outside the city. Power from these sites is transmitted into Chicago at high voltage, and is made available to the 66-kv interconnecting system in the city. This situation has a considerable effect on the economics of the subtransmission system, because it makes more favorable the use of 66 kv as a subtransmission voltage to deliver the power closer to the point of utilization. Present indications are that the trend towards power being made available in the city at a higher voltage will continue.

Paper 49-172, recommended by the AIEE System Engineering and Transmission and Distribution Committees and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer General Meeting, Swampscott, Mass., June 20-24, 1949. Manuscript submitted March 2, 1949; made available for printing April 29, 1949.

K. M. SMITH is System Planning Engineer and E. L. MICHELSON is Section Engineer, both with the Commonwealth Edison Company, Chicago, Ill.

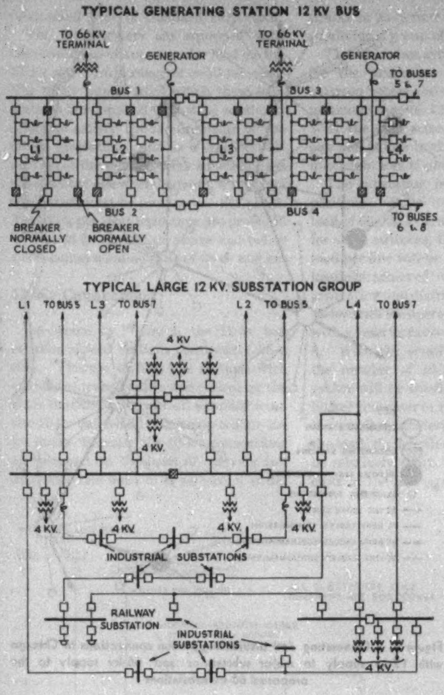

Figure 1. Generating station 12-kv bus and 12-kv substation connections

2. The present 12-kv lines average about four miles in length, and the longest lines extend eight to ten miles from the switchhouse. With rapidly increasing load density, particularly in areas remote from the present switchhouse sites, continued subtransmission from these sites at 12 kv involves considerable costs, and the need for a higher voltage is indicated.

3. In recent years there has been an extensive development of factory assembled switchgear, which has many attractive features. Switchgear of this type, in a price class which makes it suitable for substation use at 12 kv, has been made available in interrupting capacities as high as 500,000 kva. A plan which would permit the integration of this type equipment into the system appeared desirable.

In the light of these developments, and as the need for 12-kv switch positions for subtransmission purposes has increased, various studies have been made of the economies of extending the 66-kv system for subtransmission purposes. Instead of constructing additional large switchhouses, or extending present ones, consideration was given to the use of smaller 66/12-kv substations of simplified construction which would be supplied from 66-kv lines and be superimposed on the existing pattern of 12-kv subtransmission. Investigation disclosed the following advantages for the use of the smaller type of 66/12-kv installations:

1. It has been the experience that the large switchhouses designed for 40 to 60 line positions have a costly development period due to the necessity for constructing the station in large increments. As a result, it may take many years to obtain full utilization of the capacity of the switchhouse. The use of smaller substations permits a closer match between system requirements and actual construction.

2. The use of 66-kv reduces the amount and cost of cable required for subtransmission purposes. The small 66/12-kv substation permits extending the 66-kv lines close to the center of the load, with the result that the lines between the 66-kv substation and other substations requiring 12 kv in the vicinity are relatively short. In addition, if the 66/12-kv substation can be located adjacent to an existing major 12/4 kv-substation, 12-kv lines for the latter are eliminated completely.

3. With the larger switchhouses, involving as many as 60 12-kv cables and the various 66 kv, and possibly 4 kv, cables required for the station, the problem of cable congestion in the streets adjoining the station can become a serious problem. In some cases the number of possible conduit runs is rather limited, and the cable congestion may lead to excessive heating with resultant reduction of cable capacities.

4. Smaller installations inherently will have a lower value of short-circuit current. While the calculated value of fault current at the larger 12-kv switchhouses ranges from 1,000,000 to 2,000,000 kva, it was found that an economical size of 66/12-kv substation could be selected which would easily restrict fault current values to 500,000 kva. This makes possible the use of low interrupting capacity switchgear. It also makes possible the elimination to a large extent of 12-kv line reactors which are required on lines emanating from the larger switchhouses.

5. Substations are more adaptable to supervisory control than large switchhouses due to the simplicity of the layout and the smaller amount of load being supplied from the station. As a result, the operating costs for a 66/12-kv substation of relatively small size can be kept to a minimum.

6. The smaller 66/12-kv substations provide improved reliability for the 12-kv system by reducing the number of 12-kv lines to one location. To the extent that a switchhouse is subject to complete outage from fire, explosion, and other similar occurrences, the reduction in the number of 12-kv lines originating at one location should reduce the severity of any one case of trouble.

New 66/12-Kv Substations

The growth of load in Chicago during the recent war and postwar period resulted in prospective full utilization of some 12-kv switchhouses. The general advantages of 66 kv for subtransmission purposes using small 66-kv substations, appeared to make the use of this voltage very attractive. Also, general economic studies, which are discussed in a later section of this paper, showed considerable savings for the 66-kv system. After a review of conditions in each specific case, it was decided to provide expansion of the subtransmission system by the construction of 66/12-kv substations, rather than by enlarging the existing switchhouses or constructing additional large switchhouses.

The installation of several small 66/12-kv substations is planned, and one of these stations was placed in service in the latter part of 1948. Figure 3 shows the existing subtransmission system with the new 66-kv lines and substations superimposed. In each case, the new 66-kv substation supplements the existing system by supplying load on the fringes of the present zones. In this manner, the great-

est reduction in the length of 12-kv lines is effected, and the maximum economy is obtained.

The following is a description of the elements of these subtransmission systems which concern the planning engineer. The general layout for one of these systems is shown in Figure 4.

Basic Capacity Elements

From a planning point of view, an important problem was the co-ordination of capacity of the various components of the system. As the 66-kv substation lines will operate as a radial system not interconnecting 66-kv transmission terminals and without 66-kv bussing at the substations, it is possible to co-ordinate line and transformer capacity on an individual line basis. The maximum size of 3-conductor 66-kv cable which may be installed in the existing duct system is 650,000 circular mils, which will have a normal summer rating of 49,000 kva, and an emergency rating of 66,000 kva. To match this line capacity, a transformer size was selected which permits the connection of two transformers per line, that is, a 3-phase unit with a 25,000 kva forced-air rating and an emergency rating of 33,000 kva. Thus, a 3-line subtransmission group will supply two substations, each with three transformers, and each having a firm capacity of 66,000 kva so that the total load will match the emergency line and transformer capacity with one line out of service. The cable between the two substations is, of course, smaller as it must serve only one transformer. Cable of 250,000 circular mils was selected for this purpose.

66-Kv Lines

All 66-kv cable is 3-conductor oil filled. At or near the first substation at the termination of the 650,000-circular-mil cable, a 3-position disconnect device is installed from which will be taken the tap to a transformer in the first substation and the 250,000-circular-mil cable supplying a transformer in the second substation. This device will permit disconnection of either outgoing tap and restoration of service to the other.

At the supply point, each of the 66-kv subtransmission lines is connected to a different bus section for maximum reliability. The use of 3-conductor cable makes it necessary to provide line reactors at this point. The reactors have a value of 3.5 ohms, which will reduce the value of fault current imposed upon the 66-kv phase isolated terminal, by a multiphase fault on the 3-conductor cable, to less than 1,000,000 kva.

Transformers

The 3-phase 66/12-kv transformers will have an impedance value of 11 per cent, based on the self-cooled 20,000-kva rating. This is the maximum impedance value available without special design. Here again, the factor of co-ordination appears, as with three transformers of the size and impedance selected, the 3-phase fault current on the 12-kv side is somewhat less than 500,000 kva, the value corresponding to the interrupting capacity of an economical type of standard switchgear.

The transformers are equipped with automatic tap changers under load on the 12-kv side with a range of ±10 per cent. The 66-kv busses from which these substations are supplied cannot be regulated solely to satisfy the requirements of the 66-kv substations, and as a considerable portion of the load on these substations is unregulated elsewhere, adequate range of regulation must be provided at this point. Two $2^1/_2$ per cent fixed taps are provided on the 66-kv windings above and below the nominal winding ratio of 66 to 12.6 kv.

12-Kv Connections

As shown in Figure 4, the 12-kv bus consists of four sections connected into a ring. The use of four bus sections with only three transformers was chosen on the basis that the units of load supplied from the 12-kv bus would require up to four 12-kv lines. Because the 12-kv connections are planned on the basis of carrying full load with one line out of service, it is desirable to have four separate bus sections supplying a group of four lines.

The 12-kv bus arrangement is designed for the maximum electrical separation between busses and transformers with the minimum use of 12-kv circuit breakers. With the arrangement shown in Figure 4, any one failure in the station will cause a maximum loss of one transformer.

The substation includes 16 12-kv line positions. Based on a maximum 12-kv load of 66,000 kva, and without allowance for spare switches, the average coincident load per line will be lower than the actual loadings achieved on existing lines from generating and distributing stations where 12-kv lines are operated in groups of eight, with a reserve ratio of approximately 1 to 8. With the smaller 66-kv substations, the number of 12-kv lines grouped together will be smaller, with consequently higher line reserve ratio. However, with the smaller substations located closer to the load, the length of each 12-kv line will be relatively short, and as the increment costs of the line circuit breakers in these substations is relatively low, the lesser line loading does not adversely influence the economics of the 66-kv subtransmission system to a serious extent.

Since the maximum possible fault current is below the capacity of the 500,000-kva circuit breakers, reactors are not required on outgoing lines to protect the substation equipment. However, line reactors will be required in a few cases to protect lower capacity circuit breakers at customer substations supplied at 12 kv from 66-kv substations.

System Grounding

The substation transformers will be delta connected on the 66-kv side, and star connected on the 12-kv side. The 12-kv winding neutral is grounded through a 3-ohm resistor, principally for the purpose of limiting the value of phase-to-ground fault current which will be imposed on the lead sheaths of the 12-kv underground cables. Resistance is used in the neutral rather than reactance

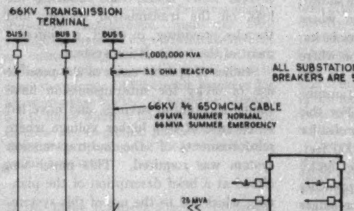

Figure 4. 66-kv supply to the new 66 kv/12-kv substations and substation bus connections

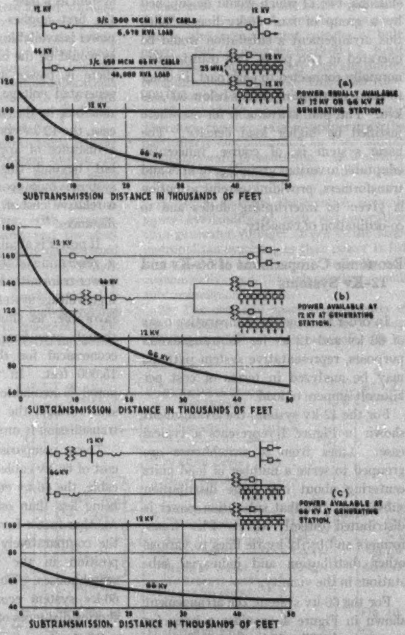

Figure 5. Comparative costs per kilovolt-ampere load 12-kv versus 66-kv subtransmission

to limit transient overvoltages in the 12-kv system.

Relay Protection

The relay protection provided for the new subtransmission system is conventional in most respects. Over-current relaying is provided on the 66-kv and 12-kv lines, and differential protection is provided for the transformers and busses. Because the substation transformers are connected to the lines without 66-kv circuit breakers, the transformer differential relays actuate a remote trip circuit to clear the remote ends of the lines. This trip circuit is incorporated at small additional cost in the pilot wire cable which is required for the oil-pressure alarm system for practically the entire length of the 66-kv cable.

Other Possible Arrangements

It is possible, with satisfactory co-ordination, to use the same units of capacity to develop 4-transformer substations, two of which would be supplied by a group of four 66-kv lines. With this arrangement a substation would be operated in two parts, two transformers normally connected to each part, in order to keep interrupting duties below 500,000 kva. This plan is available for use where justified by higher load density. The basic system is, of course, inherently adaptable to various groupings of lines and transformers, providing careful attention is given to interrupting duties and to co-ordination of capacity.

Economic Comparisons of 66-Kv and 12-Kv Systems

In order to show the comparative costs of 66 kv and 12 kv for subtransmission purposes, representative system patterns may be analyzed in terms of cost per kilovolt-ampere of load.

For the 12-kv system, the arrangement shown in Figure 1 represents a typical case. Lines from a switchhouse are grouped to serve a number of load units centering about one large distribution substation. At that substation power is distributed directly to its 4-kv transformers and by 12-kv tie lines to various other distribution and industrial substations in the vicinity.

For the 66-kv system, the arrangement shown in Figure 4 provides a basis for comparison. The 66-kv lines and transformers, in effect, replace the 12-kv lines between generating station and the load center of the group substation.

Figure 5 shows the results of the economic comparison. The 12-kv system costs include the switch position in the generating station, the 12-kv cable, and a total of three circuit breakers at the substation. The latter allocation is based on actual experience and takes into account all the circuit breakers, at each large substation, including bus ties, transformer circuit breakers, and tie lines to other substations. Since the 66-kv substation supplants all of these circuit breakers, a credit is taken for them in the cost comparison. The average maximum load per line of 6,670 kva is based on actual experience with the Chicago system. The comparable 66-kv system consists of one 66-kv line position, the 650-000- and 250,000-circular-mil 3-conductor cable, and the transformers and 12-kv circuit breakers supplied by this line. For convenience the 66-kv line is evaluated in terms of equivalent length of the larger size. The expected maximum line loading is 40,000 kva.

Figure 5 shows the relative costs of the two systems using the cost of the 12-kv system as a base. Three cases are shown; the first applies to a condition where power is available either at 12 kv or 66 kv, as would be the case at a location where there is power available either at the generated voltage or from the transmission bus in the same station. For this case, the 12-kv system has a lower cost for a distance of approximately 3,000 feet, but beyond this distance, the 66-kv system is more economical and approaches a relative cost of 50 per cent for longer distances.

If power is available only at 12 kv, as at a generating station where there is no power transmitted to the station from the high-voltage system, the 66-kv plan is less favorable, as shown by curve (b); although, even here, 66 kv would be more economical for distances greater than 15,000 feet. In the third case, where power is available only at the transmission voltage, the use of 66 kv for subtransmission is most advantageous.

These comparisons reflect the lower cost of 66-kv cable, as compared to 12-kv cable, the 66-kv cost per kilovolt-ampere being less than one-half the 12-kv cost. Another factor favoring the 66-kv plan is the comparatively high cost per switch position in the isolated phase 12-kv switchhouses. This tends to make the 66-kv system economical even for the shorter distances of subtransmission.

While these comparative studies provide a general basis for appraising the economy of the higher voltage system, there are various other practical considerations that affect the final answer. For instance, the general comparison is based on the installed cost of the 12-kv or 66-kv lines, while in actual practice any existing 12-kv lines released by the introduction of the 66-kv system will yield only salvage value. Fortunately, however, portions of such 12-kv cables can, within a short period of time, be used in place to provide for load growth in the area closer to the switchhouse. Thus, to a great extent, the actual salvage value approaches their cost in place.

The general comparison also is based on average 12-kv subtransmission line loadings. In areas remote from the switchhouse, this may not always be achieved due to the necessity for a somewhat lower loading to meet the requirements of voltage regulation. In such cases the 66-kv system has an economic advantage.

Another practical factor is the interrelationship between 66-kv subtransmission and transmission. Where the 66-kv subtransmission parallels the transmission system in the direction of power flow upon the latter, it may serve load taken from several 12-kv zones, thus reducing the load on the transmission system, and thereby providing, in effect, a reinforcement of the transmission system.

Studies of specific cases of the possible use of 66-kv for subtransmission have shown substantial savings, and have led to the use of this higher voltage where reinforcement of the subtransmission system was required. This paper has aimed at a brief description of the planning which led to the use of this system. Higher load densities, increased transmission of power into the city from outside stations, comparative costs of construction for extending existing facilities, and the availability of economical factory-assembled switchgear are primary factors which have been considered.

The gain in economy and reliability resulting from the use of the system described is evidence that time which is devoted to the planning of the subtransmission portion of a system may be well justified.

Discussion

H. R. Wall (The Commonwealth and Southern Corporation, Jackson, Mich.): The authors' interesting description of the use of higher voltage for subtransmission extensions in their territory presents a convincing demonstration of the benefits which can be obtained in this manner. Their use of radial 69-kv subtransmission supply to step-down substations, without 69-kv automatic switching at those substations, presents an economically attractive subtransmission plan.

It is noticed that the paper mentions the new extensions as "supplying load on the fringes of the present zones." It is assumed that even "fringe" territory in this location is so congested that it is not feasible to use 69-kv wood pole lines. In less congested territory where overhead lines can be used the use of higher subtransmission voltage, such as 69 kv, offers material economic advantages, since the voltage drop in the lower voltage (overhead) subtransmission circuits also is a serious consideration, as well as the thermal capacity limitations found in cable circuits. Higher voltage subtransmission might be indicated to avoid additional crowding of city streets by a greater number of low-voltage subtransmission lines.

The necessity for restricting maximum fault current on these subtransmission systems, as pointed out by the authors, with the intentional introduction of additional impedances in order to achieve that purpose, leads to a question regarding the possible use of switched capacitors for voltage control instead of, or supplementing, the tap changing underload apparatus, in order to reduce the additional losses associated with the intentionally added impedances.

The authors have mentioned the simplified relaying applied in their plan. No mention is made of the means of clearing 69-kv faults by the 12-kv circuit breakers of the step-down transformers. Since the low-voltage busses of the step-down transformers are operated in parallel, it is assumed that directional overcurrent relays are used to open the proper 12-kv circuit breakers for phase-to-phase faults. It would be interesting to know whether any provision is made to clear line-to-ground faults on the 69-kv circuits by opening the 12-kv transformer circuit breakers.

D. K. Blake (General Electric Company, Schenectady, N. Y.): It was a pleasure to read this paper for three reasons. First it is well written. I want to commend the authors for their brief and clear presentation of the pertinent factors. Second, it is encouraging and refreshing to see this departure from complications towards simplification. Third, it is a confirmation and illustration of the same economic principles that determine substation sizes whether they are for transformation from 69 kv to 12 kv or from 12 kv to 4 kv.

Some perhaps will be startled, after reading the authors' "the small 66/12-kv substation," to find they are 66,000 kva firm rating. In many other systems this would be considered "large" and would be large for those areas.

Whether a substation is large or small is not defined on economic grounds by its kilovolt-ampere rating. It is defined more properly and accurately by the area in square miles, or if one prefers, by the number and average length of the feeders departing from it. As the area decreases in size, with increasing load density, the feeder lengths to cover the area eventually become so short that a point of diminishing return is reached. There is not much left to save in 12-kv lines to offset the added substation and 66-kv extension cost inherent in diminishing substation size. Increases in load density from thereon are met by increasing the number of feeders until line or duct congestion impose their limits.

The concept of separating the load supplying function from the transmitting function in system design is a very sound procedure in my opinion and should be more widely adopted. The load supplying function is what distinguishes "distribution" from "transmission." Do the authors propose to eliminate 12-kv transformation and step from 66 to 4 kv in areas where applicable? All that is needed is enough load to economically load the 66-kv circuits and after that it becomes possible to save money by eliminating a transformation.

V. E. Hill (Duquesne Light Company, Pittsburgh, Pa.): This is a very interesting paper that has been well organized and which was easy to follow. The authors describe a principle that has become quite necessary in recent years, that is, the use of much higher transmission voltages for the distribution of power to large load centers. The plan adopted certainly has the merits of simplicity and economy. However, while going through the paper, a few questions arose.

In the reference to the use of higher voltages (that is above 66 kv) to bring power into the Chicago area from the more distant generating systems, has any consideration been given to stepping these higher voltages directly down to 12 kv? Likewise, was there any consideration given to the establishment of direct 66/4-kv substations? The latter statement assumes the installation of high capacity distribution substations in one locality. There seems to be a tendency to get away from this type of station with the use of the unit substation.

Use of 12 kv as a subtransmission voltage was, of course, quite common during the early days of the industry, because loads were light and because this was the generator voltage and it avoided the step-up transformation. However, with modern, heavily concentrated loads, and the duct congestion which is frequently encountered near generating stations or bulk supply stations, such as are described here, it is wondered whether any consideration has been given to the use of higher voltage cables, such as 22 kv in place of 12 kv.

We were very much interested in the fact that these new 66/12-kv transformers are being acquired with automatic tap changing under load. We have been checking the need of this additional control device on our 66/22-kv bulk supply stations for some years, but have not yet quite justified the cost except at one station where the voltage regulation is rather extreme. In this connection we are wondering what the regulation would be on the 12-kv busses without the tap changing under load. Are you maintaining a flat 12-kv voltage or are you adjusting it automatically by means of load compensators?

In reference to the use of four 12-kv bus sections, it was mentioned that this number was chosen because the size of the (load) units required four 12-kv lines and provision is made for one line out of service. How large are the "units" that are referred to here? That raises the question of whether there are any customers so large that they are supplied directly from the 66-kv system. The latter voltage also may be dictated by flicker limitation.

The economic comparisons in Figure 5 of the paper are very interesting and demonstrate that it is very essential to consider at what voltage the power is available.

C. A. Woodrow (General Electric Company, Schenectady, N. Y.): Any subtransmission investigation can easily become extremely complicated. Subtransmission generally includes a simple transmission function; that is, the point-to-point transfer of bulk power. But, it must go further! It must reach down and adequately feed the underlying distribution system. This latter function involves an area concept and all the ramifications of varying load density. Therefore, the authors of this paper are to be particularly complimented on their simple straightforward presentation. They clearly make two particular points which seem widely significant:

1. As in Chicago, the trend is towards power availability at high voltage rather than generator voltage. Even in the large metropolitan systems, as that power is fed down into the load areas, it logically and economically clears through relatively small subtransmission stations.

2. The cost and space requirements of the modern metalclad, 13.8-kv oil-less switch-gear (indoor and outdoor) are so

Figure 1. Alternative subtransmission patterns

attractive that they dictate subtransmission patterns which limit the 12- and 13.8-kv short circuits to 500,000 kva or less.

Though the authors have made an important contribution, a note of caution seems justified. The firm capacity of 60 to 66 megavolt-amperes may be small for 66/12-kv stations in Chicago but it is large for a great many urban areas. Quite often, considerable expense in 12- or 13-kv circuits can be saved if much smaller stations can economically and judiciously be provided within the load area. Figure 1(B) of the discussion illustrates a possible step in that direction. It provides three 40-megavolt-ampere stations as an alternate to the Chicago plan, Figure 1(A) with two 60-megavolt-ampere stations. A 2-source rather than a 3-source station is used for two reasons:

1. To reduce the number of transformers and 66-kv cable T taps.
2. It is much less costly to run two, rather than three, 66-kv laterals out into the load area to supply 40 megavolt-amperes.

As is indicated by the comparison chart of Figure 1, the principal difference in substation apparatus cost is the use of high velocity fans (or equivalent), Figure 1(B), rather than low velocity fans, Figure 1(A), on the 20-mva 3-phase transformers. However, as is illustrated by the relative cable length shown, this extra cost can often be largely eliminated. If load ratio control transformers are used, the two patterns appear to break even (real estate and underlying 12-kv cable *not* included) when the 66-kv 3-conductor cable saving of Figure 1(B) is equivalent to about two miles of cable. Without load ratio control, they break even with about one mile of cable saving.

Where the additional substation site can be made available, subtransmission pattern Figure 1(B) often warrants a serious consideration. In many cases the same pattern can be economically used to serve a total load of 80 to 90 megavolt-amperes. Correspondingly smaller subtransmission stations and smaller 3-conductor 66-kv cable would be used in these cases.

H. G. Barnett and **D. F. Shankle** (Westinghouse Electric Corporation, East Pittsburgh, Pa.): Voltages in the 15-kv class are frequently too low for subtransmission in present-day metropolitan distribution systems. Many utilities probably would adopt a higher subtransmission voltage if they did not already have extensive installations in the 15-kv range. Mr. Smith and Mr. Michelson have shown how 12-kv subtransmission can be supplemented by 66-kv circuits. The congestion and operating difficulties of the 12-kv subtransmission system are reduced by the over-all more economical 66-kv circuits. Perhaps eventually the growth of the 12-kv system can be stopped by the use of higher subtransmission voltages such as 66-kv subtransmission. Further future simplification of 66-kv underground installations may make it possible to essentially supplant the 12-kv system.

It is interesting to note that the 66-kv circuits are treated as subtransmission circuits and not as parts of the transmission system. This simplifies the operation of the system and improves the over-all economy of both the subtransmission and transmission systems.

Eric T. B. Gross (Illinois Institute of Technology, Chicago, Ill.): The authors state that it is planned to ground the 12-kv neutrals of the transformers through 3-ohm resistors, principally for limiting single-line-to-ground fault currents.

I am wondering if resonant neutral grounding has been considered. It seems to me that ground fault neutralizers would bring additional advantages; they have been used in this country in underground cable systems when no other solution promised power supply to the consumers as free from disturbances as resonant grounding.[1] The experiences have been very satisfactory.

I do not underestimate the importance of transient overvoltages, but the differences between their values at various kinds of neutral grounding are small, and should be negligible in a 12-kv system. Resonant neutral grounding has proved successful in underground cable systems at much higher voltages. Relaying of ground faults in resonant grounded systems can be done easily by means of sensitive single-phase directional relays which are activated by the residual feeder current, and polarized by the neutral displacement (zero sequence) voltage. If such relays are installed, any voltage dips are eliminated which are otherwise unavoidable on single-line-to-ground faults.

REFERENCE

1. RESONANT GROUNDING OF DISTRIBUTION SYSTEMS, E. Herzog, *Proceedings*, Midwest Power Conference, Illinois Institute of Technology, Chicago, Ill., volume 11, 1949.

K. M. Smith and **E. L. Michelson:** The authors appreciate very much the interest in their paper and the various discussions which have been offered.

Mr. Woodrow has provided an excellent example showing that in some cases it would be more economical to use a smaller substation than the one being used in Chicago. It is very possible that with lighter load densities than those existing in Chicago, the smaller substation would provide greater economy. Local conditions vary a great deal, and in any economic study these dictate the final answer. It may be of interest that in a later project in Chicago, in an area of very high load density, the substations will have a capacity of 100,000 kva. Another important factor in connection with the size of station is the difficulty of acquiring real estate in crowded city areas. This situation tends to favor substations of a larger size.

Mr. Blake and Mr. Hill both mention the possibility of 66/4-kv substations. This arrangement has been investigated, but for various reasons it has not appeared to be advantageous for the Chicago conditions. It seems that a more logical development would be the use of 12-kv for distribution purposes to replace the existing 4-kv system.

While this possibility has been seriously considered, many difficult design and operating problems for the conditions existing in the Chicago system have prevented the adoption of the higher distribution voltage.

Mr. Wall is correct in his assumption that the fringe territories referred to in the paper are sufficiently congested that it is not feasible to use overhead construction. He refers to the use of switched capacitors for voltage control, but this method is not being used in Chicago due, principally, to the disadvantages of locating these capacitors in crowded alleys. In connection with the relay protection for the 66-kv lines, directional relays are used to open the 12-kv circuit breaker for a phase-to-phase fault on the 66-kv line. In the case of a phase-to-ground fault, the ground relays at the supply end of the line energize the same remote-trip wires that are used for transformer protection, and in this manner all terminals of the line are opened for all types of line and transformer faults.

In answer to Mr. Hill's questions, the power brought into Chicago from distant generating systems now is being supplied to the 12-kv busses of the generating and large distributing stations. In the new development the only change is that the 66-kv system is carried closer to the ultimate load. The advantages gained by the use of 22-kv instead of 12-kv do not appear to be sufficient to justify a major change in the subtransmission system, due to the relatively small increase in voltage. In effect, the new system in Chicago has increased the subtransmission voltage from 12-kv to 66-kv. The 12-kv cables which are required with the new arrangement are relatively short and are not an important factor in the over-all economy. With regard to the 12-kv bus voltage at the new substations, the voltage is compensated for load, with the result that the bus voltage varies from 12-kv at minimum load to approximately 12.4-kv at maximum load. In Chicago there are a few customers supplied directly from the 66-kv system. The units of loads supplied from the new 66-kv substations in some cases may be a single customer, but in most cases consist of small substation groups which require a maximum of four 12-kv lines.

Resonant neutral grounding is not being used in Chicago at the present time. Dr. Gross' suggestion for its use in the new 66-kv substations is a very logical one, and consideration should be given to its use. However, it does not appear that this type of grounding offers any over-all advantage compared to resistance grounding when it is considered that reserve capacity is provided for all substations and 12-kv customers, and, therefore, there is practically no need to operate a cable while it is faulted.

Overcurrent Investigation on a Rural Distribution System

G. F. LINCKS

J. H. LEH
NONMEMBER AIEE

GOOD service continuity with the least possible outlay is a major problem on every rural distribution system. To make the rural line pay, the farmer must use electric power for milking machines, hay drying, water pumping, and many other tasks about the farm which affect his livelihood. With such industrialization of the farm, the average monthly consumption per consumer approaches 150 or 200 kilowatt-hours at present and is expected to reach as high as 400 or 500 in some areas in the future. Loads of these magnitudes make provision for high quality service more economically practicable.

Experience has shown that distribution primary line faults are the major cause of power service outages. Sectionalizing the line with overcurrent protective devices is an accepted procedure for economically reducing the number and duration of outages caused by primary line faults. The problem now is to evaluate numerically the benefits with different types of equipment and better protective methods.

Objective of Investigation

The objectives of the overcurrent investigation on the Central Electric Co-operative's system at Parkers Landing, Pa., during the years 1944, 1945, 1946, and 1947, were to:

1. Obtain a measure of the quality of service continuity provided to consumers.
2. Evaluate the effect of tree trimming on service continuity.
3. Gain experience with, and measure the effectiveness of, a new protective method employing overlapping operation of fuses and oil circuit reclosers to improve service continuity and to reduce restoration expense.
4. Study the effect of line length on service continuity.
5. Obtain operating data on the overcurrent protection problems at individual transformers.
6. Obtain fundamental data on overcurrents on rural circuits.

The Rural System

Characteristics of the Central Electric Cooperative's 7,200/12,470-volt 4-wire multigrounded wye rural-distribution system included long radial circuits, penetration into less densely populated areas resulting in wider separation of lightning protective equipment, and other factors which magnify the overcurrent protection problem. The Cooperative's management recognized the imperative need for improving service continuity and made the system available for experimentation in a combined overvoltage[1] and overcurrent investigation. It was believed that the data obtained would be of value to all operators of rural systems.

This system feeds an area of approximately 40 by 60 miles in the hilly country along the Allegheny River in northwestern Pennsylvania, where lightning, wind, trees, and other hazards to good service are of typical severity. Rural Electrification Administration type of line construction is employed, using practically only one make of electric equipment. In 1944, there were 1,015 miles of primary line ($87^{1}/_{2}$ per cent single phase line-to-neutral) feeding 4,178 consumers through 3,100 transformers. East and west sections of the system were fed by separate 900-kva transformer banks, supplied from the West Penn Power Company's 25-kv line. There were two feeders on each section, as shown in Figure 1. Tables I and II show the growth of the system during the period of the investigation.

The Overcurrent Protective Equipment History

As on many rural distribution systems, originally fuses alone were used to sectionalize the main feeder and to isolate faults to branches, and sub-branches. However, fuses are not capable of differentiating between nonpersistent faults, which can be cleared with only a momentary outage, and persistent faults which require the service of a line crew. The high percentage of nonpersistent faults prevalent on rural systems caused too many unnecessary outages and service trips. This led to the substitution of reclosers in the main line and on long branches. Most branches were not protected, as shown in Figure 1, since in 1944 available reclosers did not provide for coordination with fuses and to use reclosers in each branch was too costly.

Neither fuses alone nor reclosers alone even approached the desired service continuity. The need was recognized[2] for co-operative operation of fuses and reclosers in which the recloser would clear all nonpersistent faults without even partially melting the fuses, and the fuses would isolate all persistent faults to the faulted section of the line. This system, referred to as "overlapping protection," has been used successfully for many years with substation relays and line fuses.[3-4]

System Requirements Studied

In planning the investigation to use the overlapping fuse-recloser protection, the

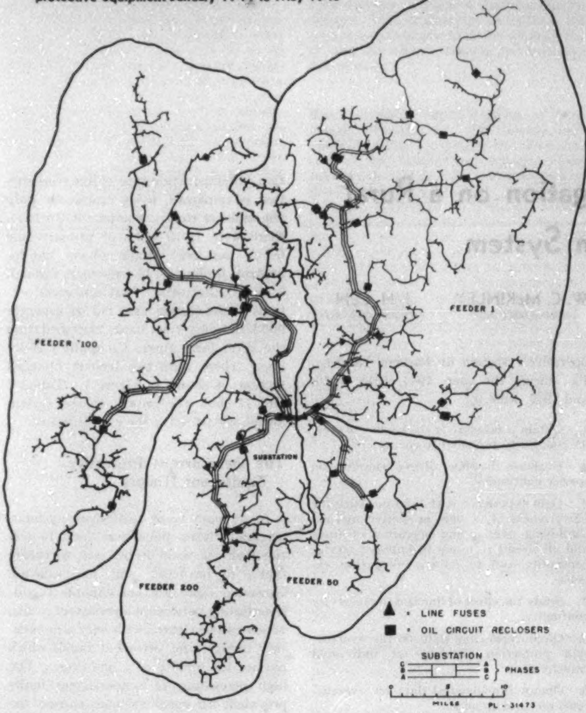
Paper 49-175, recommended by the AIEE Transmission and Distribution Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer General Meeting, Swampscott, Mass., June 20–24, 1949. Manuscript submitted November 15, 1948; made available for printing May 2, 1949.

G. F. LINCKS is with the General Electric Company, Pittsfield, Mass.; D. R. EDGE is with the Graybar Electric Company, Inc., Chicago, Ill.; W. C. MCKINLEY is with the Central Electric Cooperative, Inc., Parkers Landing, Pa.; and J. H. LEH is with the General Electric Company, Pittsburgh, Pa.

The authors wish to express their appreciation to the Board of Directors of the Central Electric Cooperative Inc., and to the line crew of the same company, as well as D. D. MacCarthy, J. W. Kalb, W. H. Eason, D. A. Stann and to Mrs. M. C. Lovejoy.

Figure 1. System map showing location of overcurrent protective equipment January 1944 to May 1945



following system requirements were apparent:

1. The overlapping protection must include the entire system from the substation to the ends of feeders and all branches. Otherwise the maximum improvements in service continuity and in reduction of restoration expense can not be realized.

2. For economical use of reclosers, each recloser should clear nonpersistent faults on as much of the feeder and connected branches as it is capable of protecting.

3. Generally reclosers, applied as in (2) will protect from 15 to 25 miles, or more, of line. Such distances are too great for quick location of faults and, at times, for the physical endurance of the crews. Thus additional sectionalizing is necessary between reclosers to isolate persistent faults. Fuses are most economical for achieving this additional sectionalizing.

4. Overcurrent protective means must be provided for the isolation of persistent faults to the faulted branch or sub-branch. Again fuses are the most economical devices.

5. All reclosers and fuses in the line must co-ordinate properly with both external and internal primary fuses at the individual distribution transformer installations. Self-protected transformers of pre-1939 manufacture, with the larger internal fuses,[5–6] were scattered all over the system. Since determination of pre- or post-1939 manufacture was not considered practicable, a minimum primary line fusing of 15 or 20 amperes for $1^1/_2$- and 3-kva transformers and 20 or 25 amperes for $5–7^1/_2$- and 10-kva ratings was necessary.

6. The same 100 per cent successful co-ordination, which has been proved practicable between fuses, must be provided in the co-ordinated overlapping protection using reclosers with line sectionalizing fuses, branch fuses, sub-branch fuses, and internal transformer fuses, all connected in series for sequential operation.

† Mileage values shown in parentheses treat three-phase and two-phase as one line. Other mileage totals add three lengths for three-phase and two for two-phase.

Overcurrent Protective Methods and Equipment

Three co-ordinated overlapping fuse-recloser protective methods were analyzed by making actual co-ordination studies on the Central Electric Cooperative system, the findings are shown in Table III.

This analysis showed the co-ordinated fuse-lock-closed recloser method (number 3) to be best. Therefore, a mechanism, Figure 2, was designed to modify the type *FP-119* reclosers in use on this rural system so the reclosers opened instantaneously twice and then they locked closed.

Because of lack of energy to reset this mechanism, it had to be reset manually after the properly co-ordinated fuse blew. This was neither as efficient nor error-proof as the reclosers designed later for automatic resetting.[9]

Co-ordination Study

It was decided to make the study on the feeder on which the lightning investigation[1] was being conducted, thus making possible the co-operative use of an automatic oscillograph, to be described later. The proper rating of reclosers and fuses were determined by a co-ordination study.

All branches from each of the main feeders were numbered using series starting with 1, 50, 100, and 200 and the feeders became known by these numerals, as shown in Figure 1. All of the subbranches were lettered on each of the main branches.

The map, Figure 3, shows the location of the reclosers and fuses and Table IV gives a history of the installations of protective equipment during 1944, 1945, 1946, and 1947.

Table II. System Growth During Investigation —Distribution Transformers and Load

Year	Average Number of Transformers	Average Kilowatt-Hours Consumed Per Consumer Per Month
1944	3,100*	81.6
1945	3,100*	91.1
1946	3,225*	100.5
1947	3,410*	150 (approx.)

* Approximately 950 of these were the conventional distribution transformers with external fuse cutouts and lightning arresters (on the first 400 miles.) All other transformers were the self-protected type with internal primary fuses and secondary circuit breakers.

Original system: 400 miles energized in August 1938 with 1,200 consumers; 400 miles energized in June 1940 with 1,200 consumers; and 300 miles energized in February 1941 with 1,600 consumers.

During this 4-year period the load increased to 184 per cent of its original value. In doing so it greatly exceeded the ultimate load for which the system was designed.

The maximum and minimum (40-ohm fault resistance) short-circuit currents were calculated using the General Electric simplified template method of calculation,[10] and were checked independently within 2 per cent by graphical calculation.[11] When checked later against oscillograph data, the calculated values proved to be slightly high. Field tests showed this to result from not factoring sufficient reductions in fault current at the substation during light load generation.[12]

The co-ordination of the reclosers and fuses was determined as follows:

1. Reclosers were located on the main feeder at, or on the source side of, the point where the calculated minimum fault current equalled the minimum pick-up current of the next recloser on the source side. Reclosers were located at the branch junction points of long branches which the main line recloser would not protect to the ends.

2. Charts were made for the overlapping fuse-recloser co-ordination, which included a correction for the cooling of the fuse link during the period between the first opening and reclosing of the recloser.

3. Existing charts[13] were used for fuse-to-fuse co-ordination.

Obtaining the Data

System Operating Data

The data originated from individual job reports of the linemen and trouble crews which were recorded in a log book

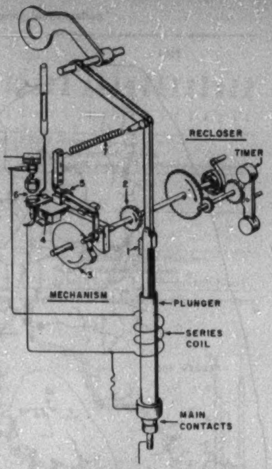

Figure 2. Mechanism modifying *FP-119* reclosers to provide two instantaneous openings to lock closed

Operation:—Fault current through series coil moves plunger up opening main contacts. When plunger resets to reclose contacts, rack 1 engages pinion 2, rotating eccentric cam 3. Second reclosing moves cam 3, so armature 4 is picked up by alnico magnet 5, closing auxiliary contacts 6, which shunt series coil and lock recloser closed. Spring 7 moves magnet 5 away from armature 4 for manually resetting mechanism

Table III

Method Number	Nonpersistent Faults Cleared Without Partially Melting Fuses by:	Sectionalizing or Branch Fuse Caused to Isolate Faulted Section by:	Findings
1	Three instantaneous openings by recloser	Going to recloser location and manually shunting the recloser with a fuse after the recloser locks open	(a) Does not save travel time and expense. Does aid in locating fault (b) Required line fuses too small (below 15 amperes) to co-ordinate with internal transformer fuses
2*	Two instantaneous openings by recloser	Two time delayed openings of recloser (lock-out of recloser clears a section of feeder on the load side)	(a) Presented a problem of co-ordination with fuse on source side (b) Sectionalizing between reclosers generally must be done with more costly reclosers. If fuses are used, it increases the number of cases under (c) (c) In some cases required line fuses too small to co-ordinate with internal transformer fuses
3*	Two instantaneous openings by recloser	Recloser locks closed until fuse blows, then resets automatically (fuse at recloser location clears a section of feeder on the load side after recloser locks closed)	(a) Co-ordination with source side fuse is no problem (b) Meets all of the system requirements outlined previously

* No commercial reclosers available when investigated. Findings were rechecked later when they became available.[7,8,9]

and on line and distribution transformer outage reports, Figure 4.

FUNDAMENTAL DATA ON OVERCURRENTS

Information on overcurrents were obtained from *GE-PM-13* automatic electromagnetic oscillographs,[14] which were in operation on feeder number 1 during the periods from April to November of the years 1945, 1946, and 1947, and on feeder number 200 from July to November 1946 and April to November 1947. Each oscillograph tripped automatically within one-half cycle and recorded all 60-cycle fault currents beyond the oscillograph in each of the 3-phase conductors, and the system neutral, as well as *A* and *C* phase voltages. Its operation was checked by periodic calibration and daily inspection and also by periodically short circuiting the ends of the line.

The System Operating Data Obtained on Primary Lines

The data, presented in a series of charts, cover persistent faults, which caused prolonged outage and required the attention of trouble crews. All parts of feeders 1, 50, 100, and 200 were protected by reclosers and thus nonpersistent faults were cleared with only a momentary outage. They were not recorded, except by the oscillographs, since the services of the trouble crews were not required. In order to interpret these results in terms of total faults, the percentage of nonpersistent faults on feeders 1 and 200 are given in Table V, as obtained from oscillograph records.

CAUSES OF PERSISTENT LINE FAULTS, FIGURE 5

The causes of persistent line faults are compared on the basis of the number per mile of line, in order to factor differences in exposure. A chart plotted on the basis of the number of faults is similar to Figure 5. Note the relatively wide variations for different years which indicates the value of several years' experience in obtaining good average data.

A comparison with other published data, on the basis of the number of faults and the percentage of the total number of faults, is given in Table VI using the terminology for causes of Gilkeson, Jenne, and Davenport.[3]

A relatively low percentage of flash-

overs were recorded as causing persistent faults, see investigation number 1, Table VI. A majority of flashovers, all whipping conductors, some tree limbs on line, and so forth, were nonpersistent faults, being cleared with only a momentary outage. Conversely, in investigation 9, Table VI, the fuses in reclosing cutouts probably were blown by some of these faults. Thus the comparison of values in investigations 1 and 9 may indicate the margin of benefit of co-ordinated fuses and reclosers versus reclosing fuse cutouts. A similar condition is indicated in Table IX showing 0.12 and 0.28 persistent faults per mile per year respectively for investigations 1 and 9. These differences would indicate an additional margin in benefits for overlapping fuse-lock-closed recloser co-ordination versus 3-shot reclosing cutouts over that shown later for overlapping fuse-lock-closed recloser co-ordination versus reclosers only.

Section 10 on "impulse blowing of fuses," Table VI, (lightning storm-blown fuses, Figure 5) is analyzed in more detail in Table VII. Fuses were considered to have been blown by lightning currents passing through the fuse to ground where there were no oscillograph records of 60-cycle current corresponding to the blowing of a line fuse during a lightning storm. If lightning arresters had been installed on each side of the line fuse, the impulse currents might have gone to ground without passing through the fuse. Thus Table VII in showing lightning blowing of fuses to be about 5.2 per cent for all the fuses on the line, represents the most severe condition.

The section on "insulator or conductor breakage," Figure 5, resulted almost entirely from irresponsible shooting by hunters.

The sections on "acts of man" in Table VI and "Trees—man, and motorized equipment" in Figure 5 are high because of extensive right-of-way clearing on the entire system in 1945, heavy logging operations along the right-of-way in 1947, and the strip coal mining carried on in the area.

"Wires down" were recorded under other causes in Figure 5 and thus is left blank in Table VI. The 78 cases of wires down are analyzed in Table VIII showing that quicker fuse blowing might have prevented burndown in only 12 cases (15 per cent). Mechanical breakage occurred in 67 per cent of the cases and may have in 18 per cent more.

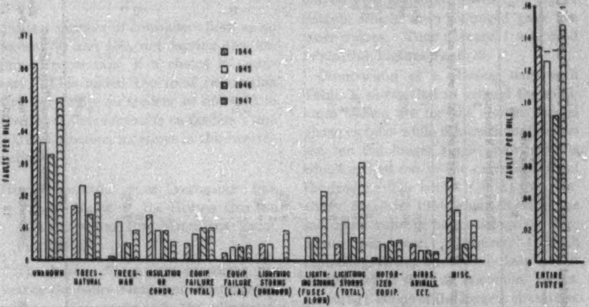

Figure 5. Causes of persistent line faults

Faults per mile of line

Exposure—Number of Persistent Faults, per Mile of Line, Figure 6

The exposure, expressed in terms of the number of faults per mile, affords a measure of the severity of overcurrent protection problems. Direct comparisons of exposure can be made for different periods on the same system or between systems provided causes of unusual numbers of nonpersistent faults are taken into consideration or only persistent faults are included, as is done in this investigation.

Note, in Figure 6, the wide variation in the exposure on different phases (single-phase circuits) of the same feeder during the same year. This shows the value of making the analysis on the basis of 12 single-phase circuits rather than just four feeders where loads and branches are predominantly single phase. This is also shown in Figures 7, 9, and 10. In the lightning investigation,[1] spot checks covering a large area on this rural system,

a Persistent faults only, requiring trouble crew.

b Persistent and nonpersistent faults recorded by oscillograph.

c Persistent and nonpersistent faults determined by counter readings on reclosers which may be high because often successive recordings are made for individual faults.

d Persistent faults only. Blowing the third fuse of reclosing cutouts by temporary faults caused recorded outages.

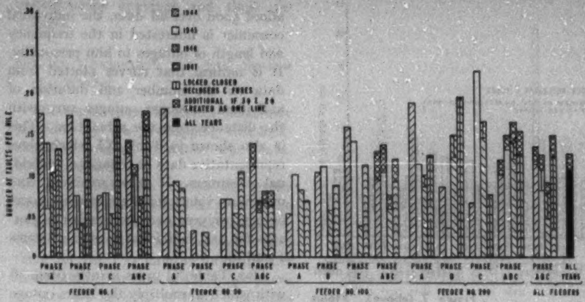

Figure 6. Exposure—Number of persistent faults per mile per year

showed wide variations in the number and severity of lightning storms even for distances of 10 or 15 miles.

The comparison of exposure with other published data, in Table IX, indicates about equal conditions to that for other systems where comparable lightning protection was employed. The "spill gaps" used for lightning protection in investigations 5, 6, and 7 naturally increased the number of faults per mile. The data in investigation 7 may be high since it is prorated to a yearly basis from data taken during the lightning period and by counter readings on reclosers which do not take into consideration successive recordings of the counter on the same fault in some cases.

Hours Out Per Outage, Figure 7

The hours out per outage for any year or period are influenced largely by whether or not there were any long outages, as shown by spot checking the data. Most of these long outages result either from long repair jobs or a fault which was difficult to locate, such as a damaged insulator. Therefore Figure 7 is not usable to compare the benefits from the use of different types of protective equipment. However, since it does show the prevalence or absence of long outages, the data in Figure 7, when combined with the exposure data in Figure 6, are extremely valuable to check the severity of fault conditions in making other comparisons.

The average restoration time curves, Figure 8, show that the "fault location time" is the only portion of the total hours out per outage affected by different types of overcurrent protection. However, when the overcurrent protection on one portion of a system markedly reduces the number of consumers affected by faults such as on feeders 1 and 200, it is natural to send the crew to take care of greatest number of consumers first, as on feeders 50 and 100, not having the improved protection, if a choice is necessary. This added the total restoration time for faults on feeders 50 and 100 to the travel time for faults on feeders 1 and 200 on numerous occasions in this investigation.

Hours Outage per Consumer Per Year, Figure 9, or Hours Outage Per Consumer Per Mile Per Year, Figure 10

The hours outage per consumer per year or the hours outage per consumer per mile per year appear to be the only measures which will define the quality of service rendered either the individual consumer or all the consumers on a circuit or system.

They are determined as follows:

$$\text{Hours Outage Per Consumer Per Year} = \frac{\text{Yearly sum of (no. of consumers affected) by (number hours out) for each outage}}{\text{Total number of consumers on circuit}}$$

$$\text{Hours Outage Per Consumer Per Mile Per Year} = \frac{\text{Hours outage per consumer per year}}{\text{Total number miles of line in circuit}}$$

The number of consumers and length of circuit existing at the first of the year were used throughout the year regardless of growth.

The only known published data using hours outage per consumer per year are those presented by W. J. Lyman[16] and a mathematical study made on a hypothetical circuit in 1941.[17] Other data, such as in references 2, 3, 16, 19 and 20 have measured the effectiveness of automatic reclosing protection by the number of momentary circuit interruptions versus the number of lockouts.

A study of Figures 9 and 10 shows the minimum and maximum hours outage per consumer per year (or per mile per year) for the 12 circuits to vary as shown in Table X.

Note that the minimum and maximum values were obtained on the same feeder and phase for both the hours outage per consumer per year and the hours outage per consumer per mile per year, except for the maximum in 1944, the minimum in 1946 and the maximum in 1947.

Average 1 in Table X, based on averaging the hours outage per consumer per year (or per mile per year) for the 12 single-phase circuits, differs considerably from average 2 (or $2'$), in which the system is treated as a unit. This difference was shown for each of the four 3-phase feeders. In average 1 only the actual number of consumers (and mileage) involved were employed for each of the 12 circuits which when averaged gave the truer values. Thus average 1 was used in plotting Figures 9 and 10.

Comparison of a phasing map with Table X shows that in general the minimum values are for the shorter single-phase circuits while the maximum values are for the longer single-phase circuits which extend out to the extreme ends of the feeder. The circuit (100A) was relatively short in 1944 when showing the minimum value of hours outage per consumer per year. However, through rephasing, it was a relatively long circuit in 1947 when showing maximum values. Circuit *1C* is one of the longest circuits on the system, but had the overlapping fuse-lock-closed recloser protection when showing the minimum hours outage per consumer per mile per year in 1946. Circuit *50A*, the maximum in 1947, while a relatively short circuit is the longest of feeder 50 and did not have the improved protection.

Some urban circuits are reported to have 1.25 hours outage per consumer per year. W. J. Lyman[20] gives the service continuity standards for his company as one hour for urban systems and two hours for rural systems. These values are well below most of those shown in Figure 9 for the early years of the investigation. This indicated considerable margin for improvement by the use of co-ordinated fuses and lock-closed reclosers if such a continuity standard was to be provided.

Outages for Individual Consumer

While studies of relative service continuity applied to the system as a whole afford good over-all data, the individual consumer is interested in the frequency and length of outages to him personally. It is natural that curves plotted from data on the number and duration of individual consumer outages vary with the distance from the substation. This is also shown in Table XI which gives representative data on outages of individual consumers. It shows minimum and maximum values for the maximum hours outage per year and the number of outages for any individual consumer (items 1 and 6).

Also, Table XI gives a ratio (item 9) with which to multiply the hours outage per consumer per year for the whole circuit to determine the maximum hours outage per year for any individual consumer. The average ratio for all four years was 3.18, with a minimum of 1 and a maximum of 9.8.

Restoration Expense, Figure 11

The manhours and mileage traveled given in Figure 11, as obtained from the weekly reports during 1947, show reductions of maintenance expense which are vitally important today. The fact that 61.5 per cent of the total line mileage for the system had the overlapping fuse-lock-closed recloser protection while only 38.5 per cent was without this improved protection, tends to make comparisons more conservative. Also, in figuring the actual costs, the assumptions of $1.25 per hour average pay for the trouble crew and the 6 cents per mile for transportation probably are low in most cases.

Determination of Benefits Obtained with Fuse-Lock-Closed Recloser Co-ordination

Hours Out Per Outage

Figure 8 shows that 1/2 hour was required to locate faults with the co-ordinated fuses and reclosers as against 1.25 hours with only the reclosers having four

Service Continuity for the System as a Whole

The improvement in service continuity provided by the overlapping fuse-lock-closed recloser co-ordination was evaluated as follows:

1. In 1945, the results on feeder number 1 for the $4^1/_2$ months prior to the installation of the fuse-lock-closed recloser co-ordination were compared with those for the $7^1/_2$ months following the installation. On each of the single-phase circuits the severity of fault conditions measured in the number of outages per mile, Figure 6, and the hours out per outage, Figure 7, were slightly greater during the period with the fuse-recloser co-ordination than without it. Thus the comparison of the values for each period in Figure 10 is conservative in showing the following very substantial reductions in hours outage per consumer per mile per year: on *A* phase—64.6 per cent; on *B* phase—88.8 per cent; on *C* phase—85.5 per cent; and *ABC* phases—80.0 per cent.

2. In 1946 and 1947, the operating data were compared for the portions of the system having each type of protection (feeders 1 and 200 versus feeders 50 and 100), since comparisons could not be made on one circuit. As pointed out, feeders 50 and 100 benefited indirectly from the overlapping fuse-lock-closed recloser protection on feeders 1 and 200, so these comparisons are conservative. The consumer hours outage per mile were reduced 67.5 per cent in 1946 with slightly more severe fault conditions indicated by Figures 6 and 7.

In 1947, 70.5 per cent of the faults per mile, shown in Figure 6, were on the portion of the system with the co-ordinated fuses and reclosers. The hours per outage, Figure 7, were approximately the same (2.5 versus 2.8). Even under these conditions there were 21 per cent less hours outage per consumer per mile per year. If the faults per mile had been approximately equal on the two portions of the system, this saving would have been about 66 per cent.

A mathematical study of a hypothetical circuit in 1941[17] showed a possible saving of 88 per cent with overlapping line protection versus no line protection.

R. O. Askey and C. V. Miller reported[21] that benefits were obtained during $1^1/_2$ years operating experience with fuses and lock-closed reclosers co-ordinated for overlapping operation on a 17-mile 7.2-kv line. They also discussed other advantages of this method of protection.

Ability to Meet Desired Service Continuity

The hours outage per consumer per year on the portion of the system with the overlapping fuse-lock-closed recloser protection in Figure 9 varied as follows on the single-phase circuits.

Feeder Number	Year	Hours Outage	Average
1	1946	3.29 to 5.9	4.2
1	1947	3.1 to 13.0	9.2
200	1947	4.5 to 6.6	5.9

These values indicate that even with the best overcurrent protection it may not be possible to meet a service continuity standard of 2 hours outage per consumer per year on all single-phase circuits or a whole 3-phase rural feeder having extremities from 45 to 60 miles from the substation.

Since feeder 50 has a maximum length of only 25 miles and received a slight benefit from quicker handling of faults, because of the improved service continuity from the protection on feeders 1 and 200, its hours outage per consumer per year was much lower, as follows:

Year	Outage	Average
1946	0.8 to 8.0	3.0
1947	0 to 7.3	2.9

With the overlapping fuse-lock-closed recloser protection, it is probable that the service continuity on this feeder would have approached a standard of two hours outage per consumer per year.

Restoration Expense

The restoration expense chart for 1947, Figure 11, shows that the co-ordinated fuses and lock-closed reclosers on 61.5 per cent of the total line mileage of the system required: 2.45 (32.8 per cent) less manhours per outage; 17.5 (26.8 per cent) less mileage traveled per outage; and $3.70 (28.5 per cent) less cost per outage.

The saving in cost per outage of $3.70 times the 138 outages per year equals $510 per year saving in out-of-pocket operating expense. Assuming a carrying charge of 15 per cent per year, the saving of $510 would justify an investment of $3,400. Assuming a carrying charge of 4 per cent per year, the same saving would justify an investment of $12,750.

The total investment in line equipment, on this rural system, to produce this saving of $510 would be $10,500. Therefore, the out-of-pocket saving alone resulting from the $10,500 investment will either carry approximately one-third of the investment or result in a net profit of $90 per year over the carrying charge, depending on the financing.

Other comparable published data, based on a mathematical study of a hypothetical circuit,[31] showed possible savings of 60 to 70 per cent in manhours and also in mileage traveled when comparing overlapping line protection with no line protection.

Table VIII. Lines Broken or Burned Down

		1944	1945	1946	1947	Total

* Figures in parentheses are single-phase circuits.

** Average 1 is based on averaging the hours outage per consumer per year (or per mile per year) for the 12 single-phase circuits.

† Average 2 is based on the total hours outage for all faults on the systems divided by the total number of consumers on the system.

‡ Average 2′ is average 2 divided by the total mileage on all the feeders.

The Operating Data on Outages at Individual Transformers

Outages at individual transformer installations accounted for 0.23 and 0.20 hours outage for every consumer on the system in 1946 and 1947 respectively. These values would be about 10 per cent of an over-all rural system performance of two hours outage per consumer per year and thus are significant. The restoration expense for outages at transformer installations, Figure 11(A) and (C) is nearly 50 per cent of the total.

Figure 12(A) shows the relationship in per cent of the total number of faults for each type of outage at individual transformer installations. Figure 12(B) shows the frequency of fuse blowings per 1,000 installations of external primary fuses at 950 conventional transformers; the blowing of internal primary fuses and the operations of secondary circuit breakers in 2,150 to 2,260 self-protected transformers.

Consumer faults or overloads on the load side of the service entrance fuses, caused the greatest number of outages; generally by opening the secondary circuit breaker. It is believed that a large percentage of the outages from unknown causes resulted from consumer faults. Probably the inability to make replacements influenced the 1946 and 1947 figures.

Lightning caused about an equal number of outages with both types of transformers. The blowing of 2-ampere fuse links at $1^1/_2$- and 3-kva and 3-ampere fuse links at 5-kva conventional transformers during lightning storms (when protected by interconnected lightning arresters located on the line side of the fuse), varied as follows:

	1944	1945	1946	1947	Average
Fuses blown by lightning in per cent of fuses installed	0	0.12	0.06	0.34	0.13

Generally 1 per cent fuse blowing during lightning storms is considered normal under similar conditions of lightning protection.

Open circuit causes resulted from mechanical breakage of secondary service wires or wires pulling loose at connection points.

Fundamental Data Obtained on Overcurrents

FAULT RESISTANCE

The data in Figure 13 should aid in determining the assumed fault resistance to be included when calculating minimum fault currents. To obtain the full protective ability of reclosers they should be located where the minimum fault current is equal to, or greater than, the minimum pickup current of the recloser on its source side. An assumed fault resistance of 40 ohms was used in the calculations for the investigation.

Figure 13 takes into consideration the lower short-circuit currents at the substation during periods of light load generation. This affects minimum fault currents and thus must be included in the calculations.[13]

INRUSH CURRENTS FOLLOWING PROLONGED OUTAGES

Inrush currents to start a high percentage of the appliance motors on a circuit can make it very troublesome in getting a circuit re-energized following a prolonged outage. The inrush currents on feeders 1 and 200 did not exceed two and one half to three times the load current and thus were not of sufficient magnitude to be troublesome. However, on several occasions it was impossible to re-energize feeder 100 through reclosers with four instantaneous openings.

Unfortunately there was no oscillograph on feeder 100 to record the currents, but undoubtedly they were higher than those recorded on feeders 1 and 200. The reclosers tripped open and, in order to establish service, had to be shunted by fuses of equivalent ratings to that used at similar points with the lock-closed recloser on feeders 1 and 200.

DIVISION OF FAULT CURRENTS IN NEUTRAL AND GROUND ON MULTIGROUNDED CIRCUITS

A study of many oscillograms of single-phase faults showed that 40 per cent of the fault current in the phase wire returned in the neutral conductor and 60 per cent through the ground. This was generally true regardless of the magnitude of the fault current except near the substation. A fault about a mile from the substation on the source side of the oscillograph initiated the oscillograph and recorded current traveling in the neutral away from the source to find a return path through ground.

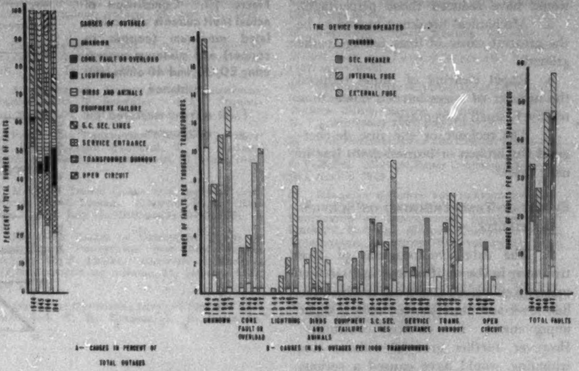

Figure 12. Outages at individual transformer installations

Conclusions

GENERAL

1. Comparison of the data on circuit conditions on the Central Electric Cooperative system with other published data indicates that this investigation was conducted on a representative rural system.

2. Three-phase systems with predominantly single-phase loads and branches can be studied and protected best if each phase is treated as a separate circuit.

3. The maximum hours outage experienced by any individual consumer varied from 1.0 to 9.8, with an average of 3.2, times the hours outage per consumer per year for that phase.

4. Blowing of primary sectionalizing or branch line fuses by lightning impulse currents, not accompanied by 60-cycle fault currents, was 5.2 per cent per year for all fuses and varied from 5 to 8 per cent for individual ratings up to 40 amperes. A lightning arrester located on each side of the line fuse undoubtedly

Superscripts 1, 2, 3, 4, 5 and 6 following items in any one year indicate that they are values for the same single-phase circuit.

would have reduced those percentages.

5. Mechanical breakage proved to be the greatest cause of lines falling to the ground.

6. Rapid clearing of faults reduced the number of wires burned down to a relatively small percentage.

7. The recloser or the fuse de-energized the broken or burned down line in most cases.

Effect of Tree Trimming on Service Continuity

8. The extensive program of tree trimming in the right-of-way in 1945 was undertaken before the trees reached the line level and thus showed only a slight improvement in service continuity. However, further growth, without this trimming, would have caused a serious increase in outages.

Effect on Service Continuity of Fuses and Lock-Closed Reclosers Co-ordinated for Overlapping Protection

9. The lock-closed recloser was shown to provide the most advantages for co-ordinated overlapping operation with several fuses in series (a) at sectionalizing points between recloser, (b) at branch junctions, (c) at sub-branch junctions and (d) at transformer installations especially of the self-protected type.

10. Such co-ordinated overlapping protection was shown to be necessary on the entire circuit in order to even approach adequate service continuity on rural distribution systems.

11. The investigation showed that fuses and lock-closed reclosers co-ordinated for overlapping protection, when applied to the entire feeder, will provide the following benefits over lines protected by reclosers only:

a. The average time to locate faults was reduced three-quarters of an hour per fault, or 60 per cent.

b. The hours outage per consumer per mile per year was reduced 70 to 90 per cent below that provided by reclosers alone.

c. The savings in restoration expense is 32.8 per cent in manhours, 26.8 per cent in mileage traveled, and 28.5 per cent in cost.

d. This conservative estimate of average yearly cost saving for restoring service will justify an investment in reclosers and fuse cutouts of $3,400 with an annual charge of 15 per cent or $12,750 with a 4 per cent charge.

This will either carry one-third of the investment, or result in a net saving of $90 per year, depending on the financing.

e. A comparison with unprotected lines or lines protected with reclosing fuse cutouts would show even greater benefits.

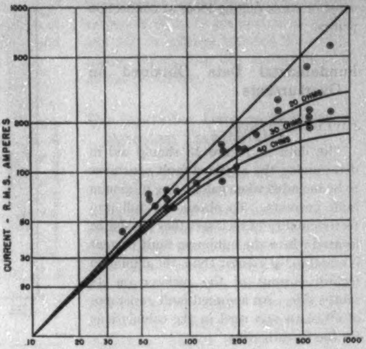

Figure 13. Comparison of actual fault currents with calculated maximum (copper to copper) and minimum currents using 20, 30, and 40 ohms fault resistance

⊙ Fault current measured on oscillogram

12. A service continuity standard of two hours outage per consumer per year does not appear to be possible, even with the fuse-lock-closed recloser overlapping co-ordination, where rural circuits extend 45 to 60 miles from the substation.

13. Such a standard appears to be possible where the greatest length of line is 25 miles and the overlapping fuse-lock-closed recloser co-ordination is employed.

14. Inrush currents following outages is not a problem with the co-ordinated fuses and lock-closed reclosers since the fusing can be high enough to prevent fuse blowing on inrush currents even if the recloser is locked closed. The recloser with four instantaneous openings did lock open and had to be shunted by fuses in order to restore service.

Effect of Outages at Individual Transformer

15. The reduction of the hours outage per consumer per year, as caused by outages at individual transformer installations is very important with both conventional and self-protected types. It can be as much as 10 per cent of the total for the system when the primary line is adequately protected.

16. Outages caused by faults on the consumers premises which cause the internal secondary circuit breakers to open or primary fuses to blow, instead of being cleared by the service entrance fuses, deserve further study as this was the largest cause of transformer outages. Such a study would weigh the increased outage time and restoration costs against the effect of better protection.

17. Blowing of 2- and 3-ampere external primary fuse links at transformer installations during lightning storms varied from 0.06 to 0.34 per cent per year, with an average of 0.13 per cent.

Fundamental Data on Overcurrents

18. The nonpersistent faults varied from 80 to 89 per cent of the total faults with an average of 84.6 per cent.

19. The assumed 40-ohms fault resistance used in this investigation, proved to be more than ample for determining minimum fault currents and might have been reduced to 30 ohms.

20. The decrease in short-circuit currents available at the substation during periods of light load generation should be factored in calculating minimum fault currents.

21. On this multigrounded neutral circuit 40 per cent of the current returns in the neutral conductor and 60 per cent in the ground. Oscillograph data showed that the ground current travels in the neutral for several pole spans in both directions from the fault, seeking a path to ground.

Discussion

C. E. Asbury (The Commonwealth and Southern Corporation, Jackson, Mich.): This paper tabulates and summarizes some very useful data for rural systems such as outage times per customer per year, the ratio of persistent to nonpersistent faults, the number of transformer failures, classification of various types of faults experienced, and so forth.

The necessity of good service continuity to rural systems is being realized more and more since the agriculturist of today depends very heavily upon his electrical servant to do many of his farm chores. The paper mentions average consumption per consumer for rural areas in that region to be in the order of 2,000 to 2,500 kilowatthours per year. Recent reports from some midwestern states with rather large rural areas show annual energy consumption in the order of 3,000 to 4,000 kilowatthours per farm customer. It is obvious that loads of these magnitudes must be given dependable service.

It should be kept in mind that all comparisons made for automatic circuit recloser performance are based on four instantaneous trips versus two instantaneous plus locked-closed operation with co-ordinated fuses.

Three overcurrent protective methods were considered for this particular application:

1. Use of automatic circuit reclosers having three instantaneous openings. We have shared the findings of the authors in attempting such applications and also find it is practically impossible to obtain any degree of co-ordination between such devices and fuses.

2. Reclosers having two instantaneous openings followed by two time-delay openings to lockout were considered but were not used for three reasons listed in the paper:

(a) It presented a problem of co-ordination with fuses on the source side. This difficulty is especially troublesome with certain makes of reclosers and fuses and emphasizes the desirability of recloser and fuse characteristics being co-ordinated in design to parallel each other. The so-called fast type of fuse having steep slope on the time current characteristics are especially troublesome in this co-ordination problem. Also, in general, fuses which are designed to melt in five minutes with current of 150 per cent rating do not co-ordinate as well with reclosers and fuses having a melting time of five minutes at the 200 per cent rating. Using fuses with different ampere ratings in the two designs to give equivalent time current characteristics is not always satisfactory because these fuses do not have the same load ability.

(b) It is not clear just what the authors mean by item 2(b) of Table III of the paper when they say sectionalizing between reclosers generally must be done with more costly reclosers. It does not appear to be good practice to consider inserting fuses between reclosers for sectionalizing in the main trunk line. In most applications, reclosers are used out on the rural line away from the substation and a station circuit breaker is used in the substation with fuses on the high side of the transformer. In the smaller rural stations, reclosers especially in the larger capacities are being used in place of the conventional circuit breakers for line protection. In such applications it is, of course, necessary to allow for the cumulative heating on the high side fuse due to recloser operations before lockout. This problem is not particularly new in co-ordination since a similar co-ordination factor must be taken into consideration where automatic reclosing conventional circuit breakers are to be co-ordinated with high side fuses.

(c) Item 2(c) in Table III states that in some cases the line fuses were too small to co-ordinate with internal transformer fuses for reclosers when two instantaneous and two time-delay shots were used. As pointed out in another section of the paper, some transformers using internal fuses are fused with rather large fuses in the order of 15 to 20 amperes which provides no protection for the transformers and such fuses are so large that it places a very definite handicap on applying sectionalizing fuses in a rural system. This is one of the disadvantages of using transformers with internal fuses. This is especially true on systems which may be electrically long where the short-circuit current may be low at the remote end of the line. With ordinary 3-kva transformers having internal fuses it is necessary that a minimum sectionalizing fuse of 25 or 30 amperes be used near the end of the circuit. Obviously, this limits the number of sectionalizing points that may be used on such a circuit and it also results in very large fuses near the station. Where conventional external fuses are used for transformers a minimum sectionalizing fuse of 15 amperes can be utilized which co-ordinates nicely with recloser applications especially when reclosers and fuses are selected having similar slopes in their time current characteristics.

Mention was made in the paper of sectionalizing fuses as well as two or three ampere transformer fuses blowing on lightning surges. It would be helpful if the authors would point out the type and characteristics of the fuses used in this particular application. Apparently, the transformer fuses were not of the newer design known as the high-surge type. Fuses classified as "fast" type are more susceptible to this type of operation than the so-called "slow" fuses. Fuses designed to have a melting time of 300 seconds with 150 per cent of rated current have much less surge ability for the same ampere ratings than do fuses designed to operate at the same time with 200 per cent of rated current. The proposed Edison Electric Institute–National Electrical Manufacturers Association (EEI–NEMA) Standard for universal fuse links is based upon all fuses being designed to have a melting time of 300 seconds at 200 per cent of rating. This should reduce considerably fuse blowing on lightning surges. Fuses designed to have characteristics within the limit described by the proposed EEI-NEMA Standard Curve *T* should present much less difficulty in blowing due to lightning surges than the so-called fast fuses described as *K* by the Standard.

The paper tabulates some comparative savings in outage time, replacement costs, traveling time, and man-hours. Again, it must be kept in mind that these comparisons are based on recloser operation with two instantaneous and locked closed performance. It is not clear in the paper on just what basis this comparison is made. Apparently, it is a comparison between two instantaneous and locked-closed recloser operations as compared with four instantaneous recloser operations or with the circuit being protected by single shot or possibly reclosing fuses. It would be helpful if the authors would state with which of the three possible comparisons the locked-closed recloser operation was compared. It must be kept in mind that such a comparison does not reflect what might be expected when using reclosers having one or two instantaneous operations followed by two time-delay operations.

The curves in Figure 13 showing the comparison of actual fault currents as compared to the calculated values with various values of resistance supplies interesting information. It is not clear just what unit the abscissa of the curve represents. How was the actual fault location for these plotted points established? It is very important that the actual location be known quite accurately in order that a misinterpretation as to fault impedance not be obtained.

It is difficult to arrive at a reasonable value of fault impedance for calculations on lower voltage systems. If too high a value of fault impedance is used, the application of protective equipment is made particularly difficult and is likely to result in applying a large number of sectionalizing devices. This is especially true as the system voltage is decreased. A fault resistance of 40 ohms was assumed for this particular investigation. If 40-ohms fault impedance is applied to systems having line-to-line voltages of 7,200 volts and less, the reach of protective devices is very short. It appears that in order to make reasonable applications of overcurrent protective devices a sliding scale needs to be used in the selection of fault impedances with lower values of fault impedance being selected for the lower voltages. It would be interesting if the authors would point out their practice in this respect and state the value of fault impedance used in lower voltage systems, such as 7.2, 4.16, and 2.4 kv.

It appears that feeders number 1 and number 200 shown in Figure 3 of the paper are considerably overburdened with sectionalizing devices. Not only does this represent an appreciable investment but is entirely too many sectionalizing devices to be co-ordinated adequately in series. On some of these feeders it appears necessary to co-ordinate 10 to 12 sectionalizing devices in series between the substations and the end of the feeders.

The information outlined in this paper on performance of reclosers having four instantaneous trips or two instantaneous trips and locked-closed operation with the particular fuses used in the application should be useful to the industry in making applications of similar equipment. It would be helpful if further data could be obtained from similar studies where modern reclosers having one or two instantaneous followed by one or two time-delay openings were co-ordinated with fuses having characteristics similar to the proposed EEI-NEMA Standard, especially with transformers being fused with external primary fuses of the high-surge type or with links having similar characteristics to that used for sectionalizing purposes.

G. F. Lincks, D. R. Edge, W. C. McKinley, J. H. Leh: Mr. Asbury has presented some interesting and helpful comments on our paper. As he points out, it is important to keep in mind that all comparisons of both the service continuity and the restoration expense data, were based on reclosers having four instantaneous openings with no fuse sectionalizing versus fuses co-ordinated with reclosers having two instantaneous plus a locked (or hold)-closed operation. However, it should be appreciated that equal improvements in service continuity and in reduction in restoration expense would be obtained if it were economically and technically practical to install reclosers having four instantaneous openings at all the locations where fuses and reclosers were employed in the investigation. This would hold true for any overcurrent protective equipment or combination of equipments (such as co-ordinated fuses and reclosers with two instantaneous plus two time-delay operations or reclosers with isolators or sectionalizers), provided that in themselves or co-operatively, they clear a majority of all temporary faults with only a momentary outage and isolate all persistent faults to equally short sections of the lines. The savings discussed in our paper show economic justification for the co-ordinated fuse-lock-closed recloser combination. However, these savings did not provide much margin for substituting more costly equipment, for the low cost fuses. If, for economical or technical reasons, fewer sectionalizing points are protected than we employed, the benefits in improved service continuity and in restoration expense shown by this investigation will be decreased proportionately, as is shown superlatively by the comparisons made in the investigation. As pointed out in our paper, technical difficulties would have necessitated fewer sectionalizing points with the instantaneous plus time-delay reclosers. This led to the choice of the instantaneous plus lock-closed reclosers.

If the co-ordinated fuse-lock-closed recloser combination had been compared with fuses alone (no reclosers) even greater benefits would have been shown over those given in the paper. The mathematical studies in references 17 and 22 of our paper indicate such a comparison would show only a slight change in the service continuity, but a very marked change in the restoration expense. Without the recloser to protect the fuses, they would be blown by both temporary and permanent faults causing outages to only a few customers on each branch, but necessitating many extra trips to restore service. Reclosing fuses would approach the advantages of the fuse-lock-closed recloser combination to the extent that manual replacement of fuses blown by temporary faults approaches the automatic resetting of the recloser in eliminating prolonged outages. Maintenance cost, however, probably would be prohibitive.

Mr. Asbury questions the use of fuses between reclosers for sectionalizing main trunk lines or long branches. Again this is an economic consideration. The orbit of protection (or "reach") of a recloser is bounded by the points on the main line and connected branches where the minimum fault current (limited by line impedance and fault resistance at the time of minimum generation on the system supplying the distribution circuit) equals the minimum pick-up (or tripping) current of the recloser. On a 7.2/12.5-kv multigrounded Y-circuit, the orbit can reach out 15 to 25 miles. Obviously, sectionalizing is necessary between reclosers located 15 to 25 miles apart. The function of a recloser or a fuse at this additional sectionalizing point is to isolate persistent faults. An additional recloser located within the orbit of protection of another recloser offers practically no additional benefits in clearing non-persistent faults. Thus, why pay for a recloser when a fuse will do the job equally well at one-tenth the cost. The lock-closed recloser permits the use of a fuse whereas the instantaneous plus time-delay recloser necessitates the use of a recloser. With the instantaneous-time-delay reclosers, a fuse at this additional point, which would have the correct rating to co-ordinate for the overlapping function with the recloser on its source side, would be too large to permit the recloser on its load side to lock open before the fuse was partially melted.

As to the overburdening of feeders 1 and 200 with sectionalizing devices, nearly five years operating experience has proved that:

1. The system functions successfully,
2. Any less number of devices would not provide the same improvement in service continuity or savings in restoration expense, and
3. These savings will pay from one-third to more than all the yearly carrying charges on the investment depending on the financing. To this would be added the savings from loss of revenue while the circuit is out, plus those chargeable to consumer good will.

There were a maximum of nine primary line sectionalizing devices connected in series. Seven of these installations are normal. Two installations are abnormal; one because the two main feeders branch off from a common feeder a mile from the substation, and the other, because an inaccessible portion of the line had to have a device at each end to save unnecessary hunting for troubles on snow shoes during $4^1/_2$ months each year. The furthest transformer was 67-line miles from the substation so the normal sectionalizing was approximately only one installation every ten miles of line. Shortening the lines, as suggested in our conclusions, would reduce the number of sectionalizing devices in series while permitting the same coverage.

Mr. Asbury suggests that fuse links on the source side of reclosers which melt at 200 per cent rated current in five minutes co-ordinate better with the reclosers than do fuse links which melt at 150 per cent rated current, such as were used in our investigation. Also, he indicates benefits would be obtained in reducing unnecessary lightning blowing. He is correct in these statements if he compares the fuse links only on the basis of the ratings, since then the 200 per cent rated links have a larger physical size and melt at higher currents throughout the whole range of time-current characteristics. However, they will not provide as good protection to connected apparatus. The 5-minute (300-second) melting current of a fuse link governs the overcurrent protection it affords connected apparatus and thus should be the basis of comparison between different fuse links. The rating is the maximum current the fuse link will carry continuously without causing excessive heating of the fuse cutout in which it is installed. The speed ratio (0.1 to 300 second melting currents) of fuse links having similar 300 second melting currents, governs the ability to co-ordinate with relays, reclosers, and other fuse links. This is true regardless of whether the fuse link is rated to carry continuously, say for example 25 amperes with the 200 per cent basis of rating or 40 amperes with the 150 per cent basis of rating. It may not be possible to apply the 25-ampere link where the 40-ampere link is applicable unless the 25-ampere link can carry that much more current than its rating. Similarly, the speed ratio, and not the basis of rating, affects the relative lightning blowing characteristics of different fuse links since such blowing involves high currents and short times. The speed ratio is a product of the physical design of the fuse link. It is not affected by the basis of rating except where higher melting temperature fusible metals, requiring the 200 per cent basis of rating, may handicap the designer in providing a desired higher speed ratio; the slow time-current characteristic which Mr. Asbury states, and we agree, may be beneficial.

The fuse links employed in our investigation have a speed ratio of from six to seven. The standard for universal fuse links currently being proposed by the Edison Electric Institute Subcommittee on Distribution Fuse Standardization, to which Mr. Asbury refers, have a speed ratio of six to eight for the *K* fast fuse links, and 10 to 13 for the *T* slow fuse links. Thus, the fuse links used in this investigation have practically the same ability, to co-ordinate with reclosers and the same lightning blowing characteristics as the *K* fast fuse links currently being proposed by the Edison Electric Institute, if compared on the basis of the 300-second melting currents. The fuse links, employing a tin fusible element as used in our investigation, are rated to carry more current continuously than it is possible to rate fuse links in the proposed standard, which also must include fuse links employing the higher melting temperature silver and copper fusible elements.

The lightning blowing of the 2- and 3-ampere fuse links used at conventional transformer installations in our investigation never exceeded one-tenth of one per cent of those installed, in any one of the four years. One to two per cent fuse blowing during lightning storms is considered normal on most systems having the lightning arrester ground interconnected with the secondary neutral. Thus, the margin of possible benefit was too small to warrant including Hi-Surge type of fuse link in our investigation.

Time-delay, time-current characteristics paralleling fuses would be desirable in reclosers, as suggested by Mr. Asbury, if co-ordination with source side fuses was the only problem. Also, it would be beneficial in co-ordinating the instantaneous opening of reclosers so as to prevent partial melting of load side fuses by non-persistent faults. However, parallel fuse and time-delay recloser characteristics starting directly from the minimum pick-up current permit co-ordination with only one or two adjacent ratings of load side fuses that also could be protected by the instantaneous opening of the recloser. A wider range of ratings was found necessary in order to fuse sectionalizing points between reclosers, branches, and sub-branches connected in service. Thus the time-delay characteristics of reclosers having two instantaneous plus two time-delay operations to lock out must be a compromise between the opposing characteristics which are desirable for co-ordination with source side and with load side fuses. The ability of the lock-closed recloser to eliminate the time-delay characteristic and all the co-ordination problems entailed therewith led to its choice as the best recloser function for our investigation.

With reference to the questions on Figure 13, the abscissa is the calculated maximum (copper to copper) fault current. The automatic oscillographs recorded the date and time each record was made so the reading could be related to the faults as reported by the trouble crews. The data were included only when the fault location was determined accurately. We know of no similar data which is available for other systems. However, it would appear that the fault resistance would be a function of the type of line construction or fault conditions rather than the voltage, except possibly as voltage effects the length of the short circuit path between conductors. Additional field data on this subject are very desirable, both on 7.2-kv and lower voltage circuits.

Short-Circuit Currents and Recovery Voltages on Rural Distribution Systems

THIS paper deals with the nature of short-circuit currents and of the recovery voltages that can occur on multigrounded neutral rural distribution systems. This information is useful in the design, application, and preparation of test standards of lightning arresters, fuse cutouts, oil circuit reclosers, and other protective devices for these rural systems.

The results were obtained from field tests made on an actual system and from calculations and analysis using the transient analyzer[1] or miniature system method. The transient analyzer studies were made primarily to analyze the most severe or boundary conditions obtainable. The field studies were necessarily limited in the type of circuit conditions, and represent more typical operating conditions. Several sets of field operating conditions were duplicated on the transient analyzer for purposes of comparison.

In so far as the authors are aware, this paper presents the first published data concerning measured values of recovery transient voltages on a rural distribution system and their correlation with transient analyzer measurements.

Fault currents and recovery voltages were studied on various combinations of single-phase and 3-phase circuits that included the effects of the angle of incidence of the fault on the voltage wave, of the location of the fault on the line, of the length of line, of the transformer rating, and of the type of fault—single line-to-ground or 3-phase.

The results are presented and discussed in three parts: transient analyzer study; field study; and comparison of field investigation with analyzer results and calculations. The analyzer study presents data from a representation in miniature of a multigrounded neutral rural distribution system, and the field study includes data from an actual 7,200/12,470-volt multigrounded-neutral wye rural distribution system.

Summary of Results and Conclusions

Some factors which affect the severity of transient recovery voltages experienced on rural distribution lines are:

1. The length of line remaining connected to the substation after the fault interruption. The rate of voltage rise decreases with increasing length of line. Whereas, in general, the crest recovery voltage appears to be relatively low with no line remaining connected after the fault, it increases to a maximum as line is added and then decreases with further increases in length of line.

2. Distance between substation and fault. For single, unbranched lines the crest recovery voltage generally decreases with increasing distance between substation and fault.

3. X/R ratio of the line between substation and fault. Crest recovery voltage decreases with decreasing X/R ratio of the line.

4. Arc voltage characteristics of the fault clearing device. A sharp rise in arc voltage immediately before arc extinction tends to increase crest recovery voltage of the transient.

5. Complexity of system network. Reflections from branch points and ends of branch lines influence the nature of the transient recovery voltages.

6. Magnitude of system load connected after interruption of fault current. The damping effect of load resistance reduces the magnitude of crest recovery voltages.

7. Kilovolt-ampere rating of substation transformer bank. Rate of voltage rise increases with increasing transformer kilovolt-amperes. Crest recovery voltages tend to decrease with increasing transformer kilovolt-amperes.

8. Lumped capacitance between line and ground such as substation bus structure or power factor capacitors. This will reduce the rate of voltage rise. An increase in capacitance up to certain values is accompanied by an increase in the crest recovery voltage.

The most severe recovery voltages measured on the transient analyzer were obtained on a study involving six miles of unloaded, unbranched line. This length of line was selected because shorter lengths of line, while giving more rapid rates of voltage rise, would generally result in lower crest voltages. Table I lists measurements obtained on this study for various values of substation kilovolt-amperes.

The shortest measured time to 0.9 times normal crest voltage, $T_{0.9}$, for either field or analyzer tests, was 22 microseconds. This was measured during field tests at the 900-kva substation bank with no connected line.

Crest recovery voltage, V_M, was 0.94 times normal.

The highest crest recovery voltage,

V_M, measured during field tests was 1.33 times normal.

Comparison of field measurements and transient analyzer results for similar circuit conditions show good agreement, demonstrating the accuracy of the transient analyzer in securing data on recovery voltages for rural distribution systems. Its value lies in the ability to extend circuit conditions beyond those found readily in the field.

Short-circuit currents measured in the field agree with values obtained by simplified fault calculators.[3,4]

Transient Analyzer Study

In this study the systems used in miniature represented 6,900-volt multigrounded neutral rural distribution systems. Substation transformer bank ratings of 50 to 2,000 kva were considered with the high voltage side of these transformers assumed connected to an infinite bus. The transformer reactances were taken as 5.5 per cent on their own base. Neither the effect of other transformers than the substation transformer nor the effect of capacitors for power factor correction were investigated. Except for special cases to be discussed later, no system load was represented in the miniature system.

Figure 2. Circuit for producing fault initiation and fault interruption in miniature system

The systems in miniature used in the analyzer studies were single radial lines—3-phase and/or single-phase—emanating from the substation transformer with no branch lines connected thereto. These circuits are shown in Figure 1. In Figure 1(A) the 3-phase line was built up in 2-mile sections to represent a total of six miles of line. The line constants for this circuit are given in the figure where it is indicated that two values of positive sequence or line resistance were considered, covering a range of line conductor sizes from the order of number 00 to number 8 American wire gauge. In Figure 1(B) the 3-phase and single-phase lines were built up in 10-mile sections to represent line lengths up to 70 miles. The line constants shown in this figure were based on a rural distribution system in which the single-phase lines, as well as the 3-phase lines and the neutral were number 6 copper, and in which spacings of 36 inches between the phase and neutral wires and between the phase wires were assumed.

The device used for the initiation of a fault and the removal of the fault at the first subsequent current zero, simulating the operation of an expulsion lightning arrester or a transformer fuse, is shown in Figure 2. The voltage drop across the *FG-57* tube simulating arc voltage during the period of fault current flow was made approximately zero for the tests made using the circuit of Figure 1(B). For the tests made with the circuit of Figure 1(A) no attempt was made to eliminate tube voltage drop. The device was connected to various points on the distribution lines of Figure 1 wherever it was decided to determine the nature of the recovery voltage as a consequence of the application and removal of a line-to-ground fault at that point.

In the operation of lightning arresters and transformer fuses, the fault current can be initiated at any instant relative to the 60-cycle fundamental frequency voltage. For an analytical treatment of the effect of initiating angle and circuit X/R on recovery transient severity, see Appendix I.

On the transient analyzer the angle of incidence of the fault was varied to give the maximum severity in recovery voltage, and these recovery voltage characteristics were expressed in terms of: (a) the maximum crest recovery voltage, V_M, that appears across the protective device following its operation; (b) the time, T_M, to reach crest of this transient recovery voltage; and (c) the time, $T_{0.9}$, for this recovery voltage to reach 90 per cent normal system crest voltage.

This value, $T_{0.9}$, was chosen arbitrarily in the absence of a universally accepted definition of initial rate of voltage rise. In instances where arc drop was present, T_M and $T_{0.9}$ were measured from the instant the recovery transient crossed the zero voltage axis.

In Figure 3 are shown the values of V_M, T_M, and $T_{0.9}$ as a consequence of fault current interruption at the terminals of the substation transformer. These values are for the 6-mile length of circuit, Figure 1(A), and for 3-phase transformer bank ratings of 50 to 2,000 kva. The condition of a fault at the transformer terminals with short lengths of connected line would be expected to give the most severe transient recovery voltages. These results indicate that V_M decreases with increasing kilovolt-amperes of the transformer bank from 1.75 times normal for a 50-kva bank to 1.28 times normal for a 2,000-kva bank. Values of T_M and $T_{0.9}$ decreased with increasing kilovolt-amperes of the transformer bank and reached values of 140 and 80 microseconds respectively for a 2,000-kilovolt-amperes bank.

To study the effect of longer lengths of line remaining connected after fault clearing and variation in fault locations, the circuit of Figure 1(B) was used. The results are shown in Tables II and III. Some of these results also are presented graphically in the curves of Figures 4, 5, and 6. The data of Tables II and III for remaining connected lines of 10-mile lengths or greater, show the following:

1. Maximum crest voltage, V_M, decreases as the number of miles of remaining connected single-phase line increases. For a fault at the terminals of a 500-kva bank, V_M for 60 miles of connected line is about 84 per cent of that for 20 miles of connected line.

2. Maximum crest voltage, V_M, decreases as the distance between the fault and the substation transformer increases. For a 60-mile line supplied through a 500-kva bank, V_M for a fault at the end of the line is 69 per cent of that for a fault at the transformer terminals.

3. In general, T_M and $T_{0.9}$ increase as the distance between the fault and the step-down transformer is increased. For a 60-mile length of remaining connected line supplied through a 500-kva bank, $T_{0.9}$ for a fault at the end of the line is 1,530 per cent of that for a fault at the substation.

It was found that the addition of single-phase line in the two unfaulted phases had very little effect on the recovery voltage of the faulted phase. This was because the only between-phase mutual coupling in the miniature system studied exists in the short 10-mile section of 3-phase line. Therefore, any unbalance

between phases would not be expected to change the recovery voltage characteristics on any one phase.

Field Investigation

Description of System

This study was made as part of a comprehensive field investigation[5,6] in cooperation with the Central Electric Cooperative, Inc., in western Pennsylvania, on their 7,200/12,470-volt multigrounded wye rural distribution system. Figure 7 is a map of that portion of the system and substation bank upon which these tests were made.

The 3-phase substation transformer bank is rated 900-kva, 4.01 per cent impedance.

As Figure 7 shows, the system basically consists of long single-phase lines branching from 3-phase feeders. Forty-two miles of 3-phase, and 524 miles of single-phase 7,200-volt line were involved.

Figure 10. Oscillograms of voltage transients obtained during field tests

Method of Test

Faults were produced at the substation and at points designated by 1, 2, and 3 on Figure 7. Figure 8 illustrates the method of applying faults and of measuring currents and recovery voltages. The 3-element moving film cathode-ray oscillograph[2] was used to measure the transient recovery voltages at fault clearing. The General Electric *PM-13* automatic magnetic oscillograph[2] measured phase and neutral currents at the fault. A second *PM-13* magnetic oscillograph located near the substation recorded phase and neutral currents (normal load as well as fault currents) and two of the 3-phase voltages.

Faults were initiated by means of a switch which was capable of simultaneous closing in the case of 3-phase faults. Fault current was interrupted either by blowing of line-to-ground fuse, or opening of line sectionalizing device, usually an oil circuit recloser. In this case the remaining lengths of connected line affecting recovery voltages were those on the substation side of the fault location since the line beyond the fault was disconnected by the sectionalizing device.

Test Conditions

At the substation and at Point 1 of Figure 7, both single-phase and 3-phase faults were produced. At Points 2 and 3 only single-phase faults could be produced. Table IV summarizes the conditions associated with each of the field tests.

Approximate load currents at the substation preceding initiation of faults were:

Phase *A:* 23 rms amperes
Phase *B:* 10 rms amperes
Phase *C:* 25 rms amperes

The remaining lengths of connected line shown in Table IV are composed of moderately long branches together with many short spurs as shown on Figure 7. The farthest point from the substation (3-phase + single-phase line) on the lines studied is 68 miles.

Results and Conclusions

Table IV shows the average recorded fault currents and the characteristics of the most severe recorded recovery transients associated with each test condition. These results indicate:

1. Fault current decreases as expected with increase in distance between fault and substation.

2. Rate of voltage rise in the recovery transient decreases as the remaining length of connected line is increased and as the distance of fault from substation is increased. Lowest value of $T_{0.9}$ is obtained at the substation with no remaining connected line and is 22 microseconds.

3. There is little correlation between the

Voltage transients resulting from clearing of 3-phase fault by sectionalizing reclosers

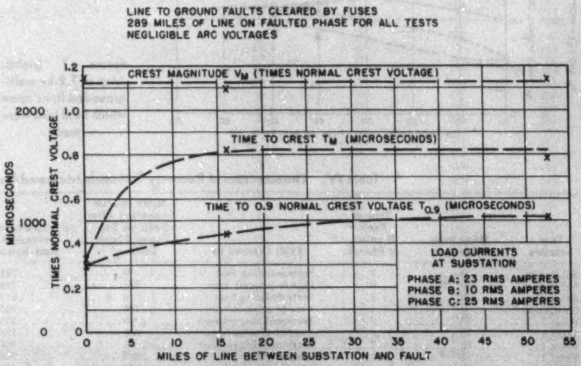

Figure 11. Effect of distance between fault and substation on recovery voltage characteristics. Field test data

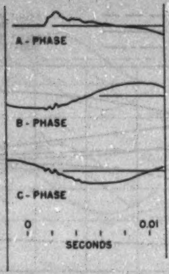

Figure 12. Oscillograms obtained during field tests at point 1. Voltage transients on phase *A* and minor disturbances on phases *B* and *C* due to coupling between phases

crest magnitudes of the most severe recovery transients and the test circuit conditions as will be discussed in a following paragraph.

4. Measured clearing angles for faults at the substation are less than 90 degrees. This results in lower restored circuit voltages and therefore the crest recovery voltages are less than the maximum possible. Clearing angle is defined as the time measured in electrical degrees by which the current zero lags the preceding voltage zero.

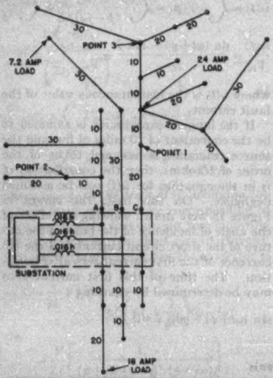

Figure 13. Miniature system used for transient analyzer study of field test conditions

Numbers represent miles of line in a given section

Table V. Symmetrical Rms Fault Current for Copper to Copper Faults

Fault Location	Miles from Substation	Type of Fault, Number of Phases	Fault Current: Measured During Field Tests	Fault Current: Using Fault Calculator *GES-3261* (Based on Measured Values at Substation)
Substation	0	3	748	(748)
	0	1	817	(817)
Point 1	16	3	270	270
	16	1	220	225
Point 2	18 1/2	1	130	140
Point 3	52 1/2	1	52	56

Examination of several of the oscillograms of recovery voltage transients helps explain 3 and 4 above. Figure 9 shows the cathode-ray oscillograms of recovery voltage obtained during the 3-phase fault at Point 1 which was cleared by the line sectionalizing reclosers, see Table IV. This was the maximum recorded recovery transient, V_M, of 1.33 times normal crest voltage and is seen occurring on phase *C*. Its severity is largely due to the final rapid rise in arc voltage of the line sectionalizing recloser just prior to current interruption. During most field tests, the arc voltage characteristics of the fault clearing devices were an important factor in determining magnitude of the recovery voltages. Figure 10(A) shows the oscillogram obtained during the single-phase fault at the same location, Point 1, and cleared by the same (*C*-phase) sectionalizing recloser. In this case the recovery voltage magnitude, V_M, was only 1.09 times normal crest voltage.

The reduction in magnitude, rate of voltage rise, and change in clearing angle shown in Table IV appear to be due to the change in arc voltage characteristics of the recloser between the two tests.

Figure 10(B) shows the recovery transient obtained on clearing a single-phase fault at the substation with the sectionalizing fuse. It illustrates the rapid rate of voltage rise possible under these conditions. The value of V_M is only 0.94 times normal crest voltage.

During a few of the tests, the recovery transients were modified very little by the current interrupting device, thus permitting other circuit conditions to control the transient recovery voltage characteristics. These involved faults cleared by line-to-ground fuses in which the following factors remained relatively constant.

1. Miles of connected line constant at 289.
2. Substantially no final rapid rise in fuse arc drop before current interruption.
3. Low fuse arc drop during current flow.
4. Clearing angles near most severe condition.
5. Load at substation constant at about 25 rms amperes on the faulted phase.

The oscillograms of the recovery transients are shown in Figures 10(C), 10(D) and 10(E). Results are shown on the curves in Figure 11. These results show that devices such as expulsion lightning arresters and fuses located at transformers are subjected to very moderate recovery transients with respect to both crest magnitudes and rates of rise under normal conditions anywhere on the system under study. When short lengths of line remain connected after the fault as in the case of line sectionalizing devices near the substation, more severe recovery transients may be experienced.

The effect of coupling between phases along the 3-phase line is illustrated in Figure 12. The transient voltage on *A*-phase at Point 1 resulted in the minor disturbances on the other phases.

Comparison of Field Investigation with Analyzer Results and Calculations

SHORT-CIRCUIT CURRENTS

Table V compares values of symmetrical rms fault current measured during the field tests with values obtained using a simplified fault calculator which consists of special graph paper and template.[3] Another method of calculation[4] gave values within 2 per cent of these calculated values. It may be seen that very close agreement with measured values is obtained by use of these relatively simple methods of calculation. However, a word of caution is in order. Accuracy obtained by these methods depends on the accuracy with which fault current at the substation bus is determined. Considerable variation in this value may exist as the generating capacity of the system supplying the substation is changed. For example, on the system where the field studies were made, fault current at the substation bus could vary from 509 to 865 symmetrical rms amperes for 3-phase faults and from 613 to 916 amperes for single-phase line-to-ground faults.

It is thus evident that available fault currents near the substation are not constant for a given system. This band of possible values must be considered in coordination studies of overcurrent protective devices. The variations cited are true only for this system and may or may

not be typical of other rural systems, depending upon their source of power.

RECOVERY VOLTAGES

Comparison of recovery voltage magnitudes, V_M, of Tables II and III with those of Table IV shows that maximum values obtained by the field tests were less than those of the transient analyzer tests. This is to be expected since the analyzer tests were made to show the most severe conditions on a simple, unbranched, unloaded system.

In order to investigate the effect of system loading and system complexity, and to demonstrate the ability of the analyzer to reproduce accurately transient recovery characteristics, additional tests were made. The miniature system of Figure 13 was used. While it is still a considerable simplification of the actual system as shown in Figure 7, it is much more nearly representative of that system than the unbranched lines used in the original analyzer studies. Connected system load was represented as lumped resistances at the points shown on Figure 13. The resistance on the faulted phase was varied to show its effect on system recovery voltage characteristics. The results of this study were:

1. When the miniature system approximates the actual system in complexity of branching and the damping effect of system load is represented, excellent agreement between field and analyzer oscillographic measurement of transient recovery characteristics results. Figure 14 shows three of the oscillograms obtained on the transient analyzer. A tabulation listing corresponding oscillograms from the field tests and comparative measurements are given in Table VI.

2. The damping effect of system load can substantially reduce the magnitude of system recovery voltage. This effect is illustrated by the curves of Figure 15. For example, for a fault at Point 1, 16 miles from the substation, V_M is 33 per cent greater with completely unloaded lines than with a 24-ampere load.

3. Figure 15 indicates that V_M is higher for a fault at Point 1 than for a fault at the substation. In Figures 4, 5, 6 where the complexity of the system was not represented in miniature, the highest values of V_M generally occur for faults at the substation.

These results show that both system complexity and system load are important factors in determining recovery transient characteristics and should be taken into account in transient analyzer studies.

Appendix I

For a simplified representation of recovery voltage, let there be considered the circuit shown in Figure 16, where the line or other capacitance is represented by the lumped capacitance C supplied from a 60-cycle voltage source through a source inductance L. The switch across the capacitor is used to simulate the application and removal of a fault.

Initially with the switch open the current and voltage are in a steady state relationship given by

$$\frac{i(t)}{V_m}=\frac{\cos\left(\omega t+\frac{\pi}{2}\right)}{|x_l-x_c|} \qquad \text{(where } x_c>x_l\text{)}$$

where $i(t)$ is the instantaneous value of current, V_m is the crest value of the source voltage expressed as $V_m \cos \omega t$, and x_l and x_c are inductive and capacitive reactances.

Upon closing the switch and assuming the effect of the discharge of the capacitor C through the shorting switch to be negligible, the equation to be solved is

$$Li_0+\mathcal{L}\,v(t)=(pL)\,Y(p)$$

where i_0 is the initial current in the inductance at the instant of the closing of the switch. If $v(t)=V_m \cos(\omega t+\psi)$ where ψ is the angle of switching, then

$$\mathcal{L}\,v(t)=\mathcal{L}\,Re\,V_m\epsilon^{j(\omega t+\psi)}=\mathcal{L}\,V\epsilon^{j\omega t}$$
$$=\frac{V}{p-j\omega}$$

where

$$V=Re\,V_m\epsilon^{j\psi}$$

Inverting the circuit equation and solving for the current gives

$$i_f(t)=\mathcal{L}^{-1}\,Y(p)=\mathcal{L}^{-1}\frac{V}{(p-j\omega)pL}+\mathcal{L}^{-1}\frac{i_0}{p}$$

$$\frac{i_f(t)}{V_m}=\frac{\sin(\omega t+\psi)-\sin\psi}{x_L}+\frac{i_0}{V_m}$$

where $i_f(t)$ is the instantaneous value of the fault current.

If the lumped capacitance is assumed to be the equivalent of 10 miles of line and the source reactance is assumed to be of the order of 15 ohms, then the contribution of i_0 in the equation for $i_f(t)$ can be assumed negligible. On this basis the curves in Figure 16 were drawn showing the effect of the angle of incidence of the fault in the nature of the short circuit current and the occurrence of the first current zero after initiation. The time of this first current zero may be determined by equating

$$\sin(\omega t+\psi)-\sin\psi=0$$

Table VI. Comparison of Analyzer and Field Measurements

Fault Location	Miles from Substation	Type of Fault	Miles of Line Connected After Fault	Analyzer				Field Test			
				Figure	V_M	T_M	$T_{0.9}$	Figure	V_M	T_M	$T_{0.9}$
Point 1	16	Line sectionalizing	29	14(A)	1.19	1,100	270	10(A)	1.09	660	260
Substation	0	Line to ground	289	14(B)	1.13	1,200	305	10(C)	1.15	1,480	340
Point 1	16	Line to ground	289	14(C)	1.09	1,770	1,070	10(D)	1.10	1,640	880

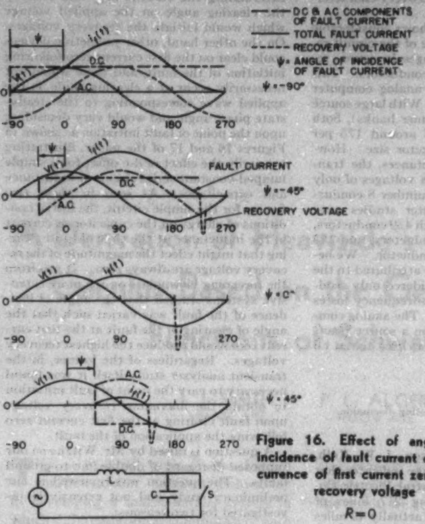

Figure 16. Effect of angle of incidence of fault current on occurrence of first current zero and recovery voltage

$R=0$

This equation is satisfied for one condition with $(\omega t+\psi)=(\pi-\psi)$, or $\omega t=\pi-2\psi$.

If the fault current is assumed to stop at its first current zero, a transient voltage appears across the capacitor. This recovery voltage may be calculated by superimposing the effects of the initial current and voltage in circuit if any upon the results obtained by the closing of a switch connecting the series circuit of L and C upon the voltage source at switching angle on the voltage wave given by the instant the short circuit passes through zero. Thus, for this case of zero initial current and voltage, the spectral equation for the current is

$$Y(p)=\frac{\mathcal{L}\,v(t)}{\left(pL+\frac{1}{pC}\right)}$$

$$\mathcal{L}\,v(t)=\mathcal{L}\,V_m\cos\,(\omega t+\pi-\psi)$$

$$=\mathcal{L}\,Re\,V_m\epsilon^{j(\pi-\psi)}\epsilon^{j\omega t}=\frac{V}{p-j\omega}$$

where $(\pi-\psi)$ is the angle of switching on the voltage wave of the source corresponding to the instant of the first current zero following the initiation of the short-circuit current. The recovery voltage across the capacitor is

$$v_c(p)=\frac{1}{pC}Y(p)=\frac{V}{pC\left(pL+\frac{1}{pC}\right)(p-j\omega)}$$

$$=\frac{V}{LC}\left[\frac{1}{(p+j\Omega)(p-j\Omega)(p-j\omega)}\right]$$

where $\Omega=1/\sqrt{LC}$.

Inverting the equation and solving for the voltage gives

$$v_c(t)=\frac{V_mRe}{LC}\left[-\frac{\epsilon^{-j(\Omega t-\pi+\psi)}}{2(\Omega^2+\Omega\omega)}-\frac{\epsilon^{j(\Omega t+\pi-\psi)}}{2(\Omega^2-\Omega\omega)}-\frac{\epsilon^{j(\omega t+\pi-\psi)}}{\omega^2-\Omega^2}\right]$$

for $\Omega>>\omega$.

$$\frac{v_c(t)}{V_m}=\cos\,(\omega t+\pi-\psi)-\frac{\cos\,(\Omega t-\pi+\psi)}{2}-\frac{\cos\,(\Omega t+\pi-\psi)}{2}$$

$$=\cos\,(\omega t+\pi-\psi)-\cos\,\Omega t\cos\,(\pi-\psi)$$

The voltage at the first peak of the transient will be obtained for $t=\pi/\Omega$. Thus,

$$\frac{v_c(t)}{V_m}=2\cos\,(\pi-\psi)\qquad(t=\pi/\Omega)$$

The maximum recovery voltage in the simplified circuit occurs for the case in which the fault current was initiated at $\psi=0$ or at the crest of the voltage wave. The time to crest voltage is given by $t=\pi/\Omega$ seconds.

If it is assumed that $x_L=15$ ohms and $x_c=25{,}000$ ohms (capacitance of approximately 10 miles of single-phase line) the time to the maximum first peak of the transient of two times normal is 204 microseconds.

The results of the effect of an appreciable resistance ($R=10$ ohms) added in series with the inductance as shown in Figure 17 are given in Figure 17 for various angles of fault application. The curves are based on the fault current equation

$$\frac{i(t)}{V_m}=\frac{1}{Z}\,(\cos\,\omega t+\psi-\theta)-\epsilon^{-\frac{R}{L}t}\cos\,(\psi-\theta)$$

where

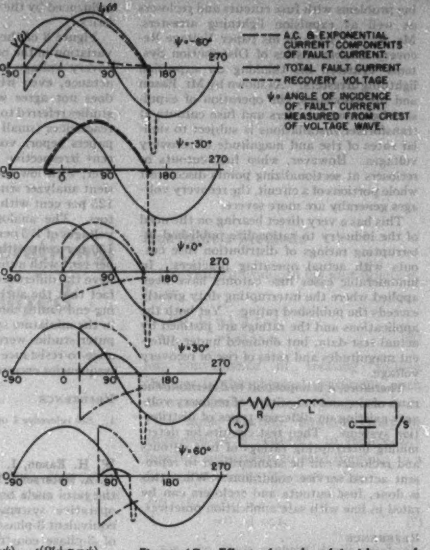

Figure 17. Effect of angle of incidence of fault current on first current zero and recovery voltage

$R=10$ ohms, $X_L=15$ ohms

$Z=R+j\omega L$

$\psi=$angle of switching, measured from crest of voltage wave

$\theta=\tan^{-1}\omega L/R$

Discussion

G. Fred Lincks (General Electric Company, Pittsfield, Mass.): The authors have recognized the broader scope of the problem of recovery voltages as it applies to the interrupting problems with fuse cutouts and reclosers as well as expulsion lightning arresters. Mr. R. L. Witzke in his paper Voltage Recovery Characteristics of Distribution Systems[1] centered his thinking on expulsion lightning arresters. As shown by Mr. Eason and his associates, the operation of expulsion lightning arresters and fuse cutouts at transformer installations is subject to similar rates of rise and magnitude of recovery voltages. However, when fuse cutouts or reclosers at sectionalizing points disconnect whole portions of a circuit, the recovery voltages generally are more severe.

This has a very direct bearing on the need of the industry to rationalize published interrupting ratings of distribution fuse cutouts with actual operating practices. In innumerable cases fuse cutouts have been applied where the interrupting duty greatly exceeds the published rating. Yet both the applications and the ratings are justified by actual test data, but obtained under different magnitudes and rates of rise of recovery voltage.

Therefore, it is important to determine the rates of rise and magnitude of recovery voltages existing on different types of distribution systems. Then test circuits for determining interrupting ratings of fuse cutouts and reclosers can be standardized to represent actual service conditions. When this is done, fuse cutouts and reclosers can be rated in line with safe application practices.

1. VOLTAGE-RECOVERY CHARACTERISTICS OF DISTRIBUTION SYSTEMS, R. L. Witzke. *AIEE Transactions*, volume 68, part I, 1949, pages 172–87.

R. L. Witzke (Westinghouse Electric Corporation, East Pittsburgh, Pa.): This paper will be useful to the industry because it contains field-test data on distribution-circuit recovery-voltage characteristics. As most recovery-voltage data are obtained from miniature-system studies, it is highly desirable to have field data available for comparative purposes. It was gratifying to see that substantial agreement could be obtained between field and laboratory results.

The Central Electric Cooperative system, on which the tests were made, has 217 miles of equivalent 3-phase circuit. This length of circuit, with its large number of branches, and the small conductor sizes are in a direction to give low recovery voltages, as compared to what might be experienced on a less extensive system. This factor should be kept in mind in the design and application of protective devices.

The transient analyzer studies reported in this paper were made by varying the angle of incidence of the fault. Analog computer studies summarized in the paper "Voltage-Recovery Characteristics of Distribution Systems," neglected this factor as unimportant because of the frequencies involved.[1] In high-frequency circuits the initiating transient usually is damped to a negligible level in a half-cycle of a 60-cycle wave, and consequently cannot contribute appreciably to the recovery transient.

The authors have given no consideration to double line-to-ground faults. As these faults may be more severe than single line-to-ground faults, they should not be neglected in the design and application of protective devices, the performance of which is influenced by the circuit recovery characteristics.

Figure 3 of the paper shows considerable variation in the magnitude of the circuit recovery voltage with changes in source reactance, even with 2/0 conductors. This does not agree with our analog computer studies referred to earlier. With large source reactances (small transformer banks), both papers report voltages of around 175 per cent irrespective of conductor size. However, with low source reactances, the transient analyzer studies show voltages of only 125 per cent with 2/0 or number 8 conductors. The analog computer studies gave voltages of 175 per cent with 4/0 conductors, 150 per cent with 2/0 conductors, and 125 per cent with number 6 conductor. We believe the differences can be attributed to the fact that the authors considered only sending-end faults, and to high-frequency losses in the miniature systems. The analog computer studies were based on a source reactance-to-resistance ratio of at least ten at all frequencies encountered.

REFERENCE

1. See reference 1 of the preceding discussion.

W. H. Eason, I. B. Johnson, J. W. Kalb, H. A. Peterson: Mr. Witzke indicates that the tests made on the Central Electric Cooperative system involving 217 miles of equivalent 3-phase circuit (actually 42 miles of 3-phase construction and 524 miles of single-phase multibranched lines) was such as to give low recovery voltages as compared to what might be experienced on a less extensive system. While, in general, this is true, it is also true that the results obtained for the complete system were lowered somewhat by loads at the time of testing as illustrated in Figure 15 of the paper; it is also true that results also were obtained on this extensive system involving shorter portions subsequent to the clearing of the fault, such as 29 and 0 miles of line connected to the substation transformer as indicated in Table III of the paper. In these tests with less extensive system connections, recovery voltages were also relatively low, particularly for the case of 0 miles of line connected to the transformer where it had been expected that the worse recovery voltages would occur rather than those obtained which did not exceed normal crest line to neutral voltage. For this latter case, a factual evaluation and understanding of the attenuation factors producing these results have not, at present, been accomplished—but are being studied. However, we feel that the system and the results obtained therefrom, both in the field and on the analyzer, are representative of a typical rural distribution system.

Another comment is made regarding the fact that the transient analyzer results were obtained by varying the angle of incidence of the fault which was not done in Mr. Witzke's studies on the analog computer because it was assumed the initiating high-frequency transients would be damped to a negligible value and would not contribute to the recovery transient. In studying recovery transients as related to various protective devices for distribution systems, some of these could clear the fault under relatively steady-state conditions where the phase-angle relationship between current and voltage imposed by the circuit would be the defining factor in determining the current zero and thereby the clearing angle on the applied voltage which would initiate the recovery voltages. On the other hand, other protective devices could clear on the first current zero following initiation of the fault, and these would not necessarily occur at a clearing angle on the applied wave corresponding to the steady-state phase angle and would vary depending upon the point of fault initiation as shown in Figures 16 and 17 of the paper, illustrating primarily the effect of d-c offset for a simple lumped-constant series circuit of inductance and capacitance. As seen in these two figures for the simple circuit, the initial conditions of charge on the capacitor or current in the inductance at the time of fault clearing that might effect the magnitude of the recovery voltage are always zero. It was from the foregoing viewpoints on the more extensive systems studied that the angle of incidence of the fault was varied such that the angle of clearing of the fault at the first current zero would produce the highest recovery voltages. Regardless of the former, in the transient analyzer study itself it was found necessary to vary the point of fault initiation to obtain the maximum recovery voltage upon fault clearing at the first current zero following the application of the fault.

A question is raised by Mr. Witzke on our supposed disregard of double line-to-ground faults. The question was reviewed in our preliminary study and not extensively investigated for two reasons:

1. Rural distribution systems of the type studied are predominantly single-phase except for some short 2-phase and 3-phase sections near the substation.

2. Multigrounded neutral rural distribution systems should have ratios of X_0/X_1 not appreciably greater than one, and it is for those systems where this ratio is appreciably greater than one where double line-to-ground faults become more severe than single line-to-ground faults and should not be neglected.

Lastly, Mr. Witzke mentions a disagreement in the magnitude of the recovery voltages between those obtained on the analog computer and those obtained on the transient analyzer for the conditions of low source reactance and short lengths of line with different size conductors. With low source reactance, the transient analyzer gave results of the order of 125–130 per cent maximum recovery voltages for short lengths of line having conductor sizes ranging from number 8 up to 2/0. Analog computer studies gave results of 125 per cent for number 6 conductor, increasing to 150 per cent for 2/0 conductor. For the smaller size line conductors, the conclusions from the two sets of data appear to be in good agreement. For the larger size conductors approaching 2/0, the disagreement reaches the order of a 15 per cent difference. To the extent to which all the circuit factors actually are known precisely and included, it is a question as to whether or not this difference may not be considered a fair agreement.

In Mr. Lincks' discussion, he has emphasized the applicability of these results to design and test standards for fuse cutouts and reclosers as well as for expulsion-type lightning arresters. The material presented in this paper and in others dealing with other types of distribution systems should be utilized in considering revision of test standards to recognize the important factor of system transient recovery characteristics.

A Derivation of Heaviside's Operational Calculus Based on the Generalized Functions of Schwartz

J. J. SMITH
MEMBER AIEE

P. L. ALGER
FELLOW AIEE

THE RECENT work of the French mathematician Laurent Schwartz,[1] in developing a mathematical system in which differentiation is commutative with integration, is of great practical importance, as it enables the operational methods of Heaviside to be verified and usefully extended. Schwartz has generalized the concept of a "function" by considering it to be represented by a distribution of mass, and he has thus been able to interpret such discontinuous expressions as the Dirac function and its derivatives in ways not previously permitted by classical mathematics. These ideas provide a rigorous mathematical basis for the intuitive methods of Heaviside.

Differentiation and Integration Noncommutative

The beginning student of calculus learns that taking the derivative of a function is a "many-to-one" process. No matter what the value of the constant term, A, is, the derivative of $f(x)—A$ has the same value, $f'(x)$

$$\frac{d}{dx}(f(x)-A)=f'(x) \qquad (1)$$

He also learns that integration between fixed limits is a "one-to-one" process. With a given lower limit of integration, B, the equation

$$\int_B^x f'(x)dx=f(x)-f(B) \qquad (2)$$

is always true.

He thus comes to realize that differentiation is not always commutative with (the inverse of) integration. If we first differentiate $f(x)—A$, and then integrate the result, we get $f(x)—f(B)$

$$\int_B^x dx\frac{d}{dx}(f(x)-A)=\int_B^x f'(x)dx=f(x)-f(B) \qquad (3)$$

If we first integrate $f(x)—A$ and then differentiate the result, we obtain $f(x)—A$ again

$$\frac{d}{dx}\int_B^x(f(x)-A)dx=\frac{d}{dx}\left[\int_B^x f(x)dx-A(x-B)\right]=f(x)-A \qquad (4)$$

One consequence of this state of affairs is that solving the differential equation representing any physical problem requires finding the appropriate integration constants. In complex problems, this sometimes presents real difficulties, besides being a time-consuming process.

A little study of equations 3 and 4 shows that integration will be the reverse of differentiation, if $A=f(B)$. Practically, this requires

$$A=f(B)=0 \qquad (5)$$

It will be found that differentiation and integration are always commutative if the function vanishes at the lower limit of integration.

Heaviside's Methods

Heaviside introduced his unit function, H, or

$$\begin{aligned}1=H(t,\ t_0)&=1 \text{ if } t>t_0\\ &=0 \text{ if } t<t_0\end{aligned} \qquad (6)$$

for convenience in treating sudden changes in the physical conditions, such as a suddenlv applied voltage at $t=t_0$. This same function, however, may be employed as a "cut-off" to reduce any function arbitrarily to zero previous to a desired moment. We may write

$$\begin{aligned}H(t,t_0)f(t)&=f(t) \text{ if } t>t_0\\ &=0 \quad \text{if } t<t_0\end{aligned} \qquad (7)$$

Or, we may assume $t_0=0$, and abbreviate equation 7 to the simple form

$$\begin{aligned}Hf(x)&=f(t) \text{ if } t>0\\ &=0 \quad \text{if } t<0\end{aligned} \qquad (8)$$

Heaviside also denoted the differential operator, d/dt, by p, also using its inverse, p^{-1}, to define the integration process. This we regard as merely a convenience in writing. In this paper, we retain d/dt to emphasize that the substitution of p is purely a matter of convention.

Heaviside[2] states:

> "The reader may have observed . . . . . that we change the order of operators at convenience, as in
>
> $$(p)g(p)1=g(p)f(p)1 \qquad (9)$$
>
> and that it goes. But I do not assert the universal validity of this obviously suggested transformation. It has, however, a very wide application, and transforms functions in a remarkable manner. Reservations should be learned by experience."

The classical objection to this statement of Heaviside is given by the following example.* Let $f(p)=p^m$, representing m successive differentiations, and $g(p)=p^{-n}$, representing n successive integrations.

Then, it is reasoned

$$p^m1=\frac{d^m1}{dt^m}=0 \qquad (10)$$

Paper 49-184, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer General Meeting, Swampscott, Mass., June 20-24, 1949. Manuscript submitted March 23, 1949; made available for printing May 3, 1949.

J. J. Smith and P. L. Alger are with the General Electric Company, Schenectady, N. Y.

* It should be noted that in this paper we consider only whole integrations and differentiations. Fractional differentiation will be considered in a subsequent paper.

$$p^{-n}1=\int^{t}\int\int_{n}\int\ldots 1\,dt^{n}=\frac{t^{n}}{(n)!} \qquad (10A)$$

if we consider only values of t greater than zero, for which the unit function is unity.

From equations 10 and 10(A), if $m<n$

$$f(p)g(p)1=p^{-(n-m)}1=\frac{t^{n-m}}{(n-m)!} \qquad (11)$$

Or, if $m>n$

$$f(p)g(p)1=p^{m-n}1=0$$

But, for all values of m and n

$$g(p)f(p)1=0$$

since when the differentiation is performed first, the zero answer of equation 10 is not changed by subsequent operations.

The reply to this objection is that classical mathematics leaves out of consideration the discontinuity of the unit function 1 at $t=0$, on the assumption that the derivative does not exist at such a point.

The discrepancies are cleared up if this derivative is properly interpreted, as will be seen in the discussion following equation 19. Thus, the use of the unit function, while solving the problem of making differentiation and integration generally reversible, introduces the new problem of taking discontinuities into account. Schwartz now has provided the solution for this second problem.

The Contribution of Schwartz

Schwartz states in the introduction of his 1945 paper:

> "Since the introduction of operational calculus, physicists have commonly employed certain concepts, or certain formulas, whose success has been incontestable, even though they were not justified mathematically. Thus, the function $H\ (t)$ of the real variable t, equal to zero for $t<0$, to one for $t>0$, is usually considered as having for its derivative the 'Dirac function,' $H'(t)=\delta(t)$, that is zero for $t\neq 0$, equal to $+\infty$ for $x=0$, and is such that, besides
>
> $$\int_{-\infty}^{\infty}\delta(t)dt=+1 \qquad (12)$$
>
> "Such an 'abuse of language' is entirely incompatible with the usual concept of a function and its derivative! And what should we think of considering successive derivatives of the Dirac function!"

The essence of the Schwartz method lies in considering the Dirac function as being represented by a unit mass placed at the origin, giving it a physical reality in "mass space." By conducting the desired mathematical operations in this mass space, and then transforming the result back into function space, he avoids any direct dealing with infinities.

Schwartz considers a set of continuous infinitely differentiable functions that are zero outside of a finite interval, that is, functions $\phi(t)$, such that

$$\begin{aligned}\phi(t)&=0 \text{ if } t<-k_1\\ &=0 \text{ if } t>+k_2\end{aligned} \qquad (13)$$

He multiplies the function $f(t)$, with which it is desired to deal, by $\phi(t)$, and integrates from $-\infty$ to ∞, calling the result a "functional," $f(\phi)$

$$f(\phi)=\int_{-\infty}^{\infty}f(t)\phi(t)dt \qquad (14)$$

Then $f(\phi)$ is the representation of $f(t)$ in mass space, where $\phi(t)$ is any function satisfying the conditions stated above. Inversely, if the right-hand side is obtained as the representation in mass space, then the function it represents is $f(t)$.

Similarly, replacing f by f', the representation of the derivative in mass space, if f' exists, is

$$f'(\phi)=\int_{-\infty}^{\infty}f'(t)\phi(t)dt \qquad (15)$$

Integrating equation 15 by parts, we obtain

$$\int_{-\infty}^{\infty}f'(t)\phi(t)dt=[f(t)\phi(t)]_{-\infty}^{\infty}-\int_{-\infty}^{\infty}f(t)\phi'(t)dt \qquad (16)$$

By equation 13, however, $\phi(t)=0$ at both ∞ and $-\infty$, so that the first term on the right-hand side of equation 16 drops out, leaving

$$\int_{-\infty}^{\infty}f'(t)\phi(t)dt=-\int_{-\infty}^{\infty}f(t)\phi'(t)dt$$

or

$$f'(\phi)=-f(\phi') \qquad (17)$$

The above is straightforward when $f(t)$ is continuous and $f'(t)$ exists. When $f(t)$ is not continuous, $f'(t)$ "does not exist" at the point of discontinuity. However, $df(t)$ does exist in general at this point and is equal to the jump or "saltus" of $f(t)$ at this point. In such cases Schwartz replaces the Riemann integral in equation 15 by the Stieltjes integral

$$f'(\phi)=\int_{-\infty}^{\infty}\phi(t)df(t) \qquad (18)$$

and, by integrating by parts as before, it is found that

$$f'(\phi)=-f(\phi') \qquad (17)$$

Thus equation 17 holds not only when $f(t)$ is continuous but also when it is discontinuous.

As an example, we may find the representation $\delta(\phi)$ of the Dirac function $\delta(t)$ in mass space. Putting H for $f(t)$ in equation 17 we have

$$\begin{aligned}\delta(\phi)=H'(\phi)=-H(\phi')&=-\int_{-\infty}^{\infty}H(t)\phi'(t)dt\\ &=-\int^{\infty}\phi'(t)dt=\phi(0)\end{aligned} \qquad (19)$$

This is the same result that is obtained if $f(t)$ is put equal to H in equation 18 so that $df(t)=dH$ has the value unity (unit mass) at the origin and zero elsewhere and the integration carried out. Thus the Dirac function is represented in mass space by $\phi(0)$ and it also corresponds to a unit mass dH placed at the origin. Similarly, we find

$$-\delta'(\phi)=\phi'(0)$$

and

$$(-1)^{n}\delta^{(n-1)}\phi=\phi^{(n-1)}(0)$$

Schwartz then shows that $\phi'(0)$ can be interpreted as a unit doublet at the origin and gives similar interpretations for $\phi''(0)\ldots\ldots\phi^{(n)}(0)$.

It now is evident in connection with equation 11 that putting $p^{m-n}1=0$ ignores the discontinuity at $t=0$ and that its representation in mass space is $\phi^{(m-n-1)}(0)$, in which form it is available for subsequent operations.

Since engineers are better acquainted with the Riemann integral, it may be of interest to indicate how Heaviside's use of the impulse function or its equivalent, the Dirac function, would give the same result; subject, of course, to the limitation that some of the steps may not exist in the strict mathematical sense. In this case, we would write $\delta(t)$ for $f(t)$ in equation 14 and obtain

$$\delta(\phi)=\int_{-\infty}^{\infty}\delta(t)\phi(t)dt=\phi(0) \qquad (20)$$

on making the usual assumption that $\delta(t)$ is zero everywhere except at $t=0$ where it is infinite in such a manner that its integral from $0-\epsilon$ to $0+\epsilon$ is equal to unity.

Application to a First-Order Differential Equation

To illustrate the application to differential equations, a simple example will be taken so that the procedure will be clear. The problem will be solved by three methods so that similarities and differences between methods will be apparent:

1. Ordinary mathematical method.
2. Heaviside method.
3. The Schwartz transformation method.

The problem to be solved is:

A voltage E is applied at the time $t=0$ to a circuit containing resistance R and inductance L in series. The current in the circuit is zero when $t<0$. Find the current when $t>0$.

ORDINARY MATHEMATICAL METHOD

In the ordinary method of solution we write

$$L\frac{di}{dt}+Ri=E \tag{21}$$

This is the basic form of a linear differential equation of the first order and first degree. The standard mathematical method gives the following solution, which involves the constants of integration C and C_1 which have to be determined.

$$i=C+C_1\epsilon^{-Rt/L} \tag{22}$$

From this, when $t=\infty$ we reason, that $di/dt=0$ and hence

$$C=E/R \tag{23}$$

It then is reasoned that since energy is stored in the inductance and we cannot have an instantaneous change of energy, which would require infinite voltage, i must be the same immediately before and after $t=0$, and thus, from equation 22 and the initial conditions

$$C=-C_1 \tag{24}$$

From this

$$i=E(1-\epsilon^{-Rt/L})/R \tag{25}$$

when $t>0$

and we were given as one of the conditions of the problem that

$$i=0 \tag{26}$$

when $t<0$

In this method of solution it will be noted that we had to determine the value of i at $t=0+\epsilon$ by an additional fact, such as the energy consideration above, which was not contained in the original statement of the problem. While this may not have been difficult in the above case, it does become a problem for an equation of the nth order, where n constants of integration have to be evaluated.

HEAVISIDE METHOD

In the Heaviside method we note, first, that it is given that the voltage and current are zero when $t<0$. To ensure this we introduce the Heaviside unit function and write the current in the form iH and the voltage in the form EH, where, for convenience in writing, H is the Heaviside unit function whose value is zero when $t<0$ and is equal to unity when $t>0$, equation 8.

We therefore write the equation in the form

$$L\frac{d}{dt}(iH)+RiH=EH \tag{27}$$

and take the solution for this to be

$$iH=(C+C_1\epsilon^{-Rt/L})H \tag{28}$$

where $-\infty<t<\infty$ and the presence of H ensures that the current is zero when $t<0$. Substituting this value of iH in equation 27, two of the terms cancel out, and we obtain

$$CRH+(C+C_1\epsilon^{-Rt/L})LH'=EH \tag{29}$$

where $H'=dH/dt$. This equation is really two separate equations, one including all terms having the factor H and the other including all terms having the factor H'. By equation 12, H' is zero at all values of t except $t=0$. Thus, when $t\neq 0$ equation 29 still must be valid after the terms including H' are removed. Therefore, taking the terms involving H only gives

$$C=E/R \tag{30}$$

and taking the terms involving H' only gives

$$(C+C_1\epsilon^{-Rt/L})H'=0 \tag{31}$$

From this the coefficient of H' must be zero when $t=0$, since for this value of t, H' is not equal to zero. Hence

$$C+C_1\epsilon^{-Rt/L}=0 \tag{32}$$

when $t=0$, or

$$C=-C_1 \tag{33}$$

Substituting equations 30 and 33 in equation 28 we obtain

$$iH=E(1-\epsilon^{-Rt/L})H/R \tag{34}$$

The difficulty with the above method is, of course, that H' is not a function in the accepted sense of the word. $H'=0$ when $t\neq 0$, but when $t=0$ it must be infinite in such a way that its integral

$$\int_{-\epsilon}^{0+\epsilon}H'dt=1$$

For this latter reason, the mathematicians say "it does not exist at $t=0$." This impasse can be overcome readily by the method of Schwartz, by carrying out our operations in mass space where the counterpart of H' remains finite and interpretable. Having thus detoured around the use of H', we transfer back from the mass space to the function space and find the result checks exactly with that given, using the straight Heaviside method, as will be illustrated now.

SCHWARTZ TRANSFORMATION METHOD

Let us now consider the same problem using the methods developed by Schwartz. We start with the same equation

$$L\frac{d}{dt}(iH)+RiH=EH \tag{35}$$

Assume as before a solution of the form

$$iH=(C+C_1\epsilon^{-Rt/L})H \tag{36}$$

Then the representation of iH in mass space is, from equation 14

$$\int_{-\infty}^{\infty}iH\phi(t)dt=\int_{-\infty}^{\infty}(C+C_1\epsilon^{-Rt/L})H\phi(t)dt$$
$$=\int^{\infty}(C+C_1\epsilon^{-Rt/L})\phi(t)dt \tag{37}$$

and from equation 17, $d(iH)/dt$ is represented in mass space by

$$-\int_{-\infty}^{\infty}iH\phi'(t)dt=-\int_{-\infty}^{\infty}(C+C_1\epsilon^{-Rt/L})\times$$
$$H\phi'(t)dt=-\int_0^{\infty}(C+C_1\epsilon^{-Rt/L})\phi'(t)dt \tag{37A}$$

which, by equation 16, reduces to

$$-\int_{-\infty}^{\infty}iH\phi'(t)dt=(C+C_1)\phi(0)-$$
$$\int_0^{\infty}\frac{C_1R}{L}\epsilon^{-Rt/L}\phi(t)dt \tag{38}$$

Similarly, EH is represented in mass space by

$$\int_{-\infty}^{\infty}EH\phi(t)dt=\int_0^{\infty}E\phi(t)dt \tag{39}$$

Substituting these representations in mass space in the differential equation 35 we get

$$L(C+C_1)\phi(0)-\int_0^{\infty}C_1R\epsilon^{-Rt/L}\phi(t)dt+$$
$$\int_0^{\infty}R(C+C_1\epsilon^{-Rt/L})\phi(t)dt=\int_0^{\infty}E\phi(t)dt \tag{40}$$

This gives

$$L(C+C_1)\phi(0)+\int_0^{\infty}(CR-E)\phi(t)dt=0 \tag{41}$$

Now

$$\int_0^{\infty}(CR-E)\phi(t)dt=\int_{-\infty}^{\infty}(CR-E)H\phi(t)dt$$

is the representation in mass space of $(CR-E)H$ for all values of t, while $\phi(0)$ corresponds to a unit mass placed at the origin and zero mass elsewhere, and is the representation in mass space of the derivative of the unit function as shown by Schwartz, equation 19. Thus we have

$$CR-E=0 \tag{42}$$

Substituting this in equation 41, since $\phi(0)$ represents a unit mass at $t=0$

$$C+C_1=0 \tag{43}$$

Substituting the values of C and C_1 from equations 42 and 43 in equation 36, we find as before, in equation 34

$$iH=E(1-\epsilon^{-Rt/L})H/R \tag{44}$$

DISCUSSION OF THREE METHODS

The results obtained in equations 34 and 44 are fundamental in connection with the Heaviside operational calculus. They say that when the equation for the current is written in the form

$$L\frac{d}{dt}(iH)+RiH=EH \tag{45}$$

this equation has one and only one solution given by

$$iH=E(1-\epsilon^{-Rt/L})H/R \tag{46}$$

This comes about by recognizing that when the value of the current is substituted in the differential equation, and considering H as a function of time t, there can be no terms of the form H' or its representation in mass space on the left-hand side of the equation if there are no terms of this form on the right-hand side. This allows us to conclude from equations 29 or 40

$$C=-C_1 \tag{47}$$

In this method of solution it will be noted that it is not necessary to introduce the condition that $i=0$ when $t=0+\epsilon$ as well as when $t=0-\epsilon$, which was required in the solution by the ordinary mathematical method in equations 21 to 26. In view of the emphasis usually placed in standard mathematical procedure on the determination of necessary and sufficient conditions for a problem, it would appear that the Heaviside and Schwartz method of solution are more powerful than the ordinary mathematical method, since they do not require this added condition $i=0$ when $t=0+\epsilon$.

Application to a Second-Order Differential Equation

Before proceeding to an nth order differential equation, it may be of interest to consider a second-order differential equation from a slightly different viewpoint. As an example, we shall consider the well-known Heaviside operational expression

$$\frac{p^2}{p^2+\omega^2}H=\cos\omega tH \tag{48}$$

If we were not given the result, we could evaluate the operational expression on the left-hand side by writing it equal to iH as follows

$$iH=\frac{p^2}{p^2+\omega^2}H \tag{49}$$

This can be written in the form of a differential equation on putting $p=d/dt$

$$\frac{d^2}{dt^2}(iH)+\omega^2iH=\frac{d^2H}{dt^2} \tag{50}$$

Here, of course, we are in trouble immediately because d^2H/dt^2 is not a "function." Let us proceed, however, in the Heaviside method to assume a solution

$$iH=(C_1+C_2\sin\omega t+C_3\cos\omega t)H \tag{51}$$

We then can write formally in the Heaviside manner

$$\frac{d}{dt}(iH)=(\omega C_2\cos\omega t-\omega C_3\sin\omega t)H+(C_1+C_3)H' \tag{52}$$

where the coefficient of H' is the value of $(C_1+C_2\sin\omega t+C_3\cos\omega t)$ at $t=0$. Differentiating again

$$\frac{d^2}{dt^2}(iH)=-\omega^2(C_2\sin\omega t+C_3\cos\omega t)H+\omega C_2H'+(C_1+C_3)H'' \tag{53}$$

where now the coefficient of H' is the value of $(\omega C_2\cos\omega t-\omega C_3\sin\omega t)$ when $t=0$.

Substituting this value in equation 50 we find

$$\omega C_2H'+(C_1+C_3)H''+\omega^2C_1H=H'' \tag{54}$$

Equating the coefficients of H, H', and H'' on both sides of this equation

$$C_1=0 \tag{55}$$

$$C_2=0 \tag{56}$$

and

$$C_3=1 \tag{57}$$

Thus, substituting in equation 51 we find

$$iH=\cos\omega tH \tag{58}$$

as the solution of equation 50, and hence we verify the value of the Heaviside operational expression, equation 48.

Let us now apply the Schwartz method in solving this problem. From equations 14 and 51 the representation of iH in mass space is

$$\int_{-\infty}^{\infty}iH\phi(t)dt=\int_{-\infty}^{\infty}(C_1+C_2\sin\omega t+C_3\cos\omega t)H\phi(t)dt=\int_0^{\infty}(C_1+C_2\times\sin\omega t+C_3\cos\omega t)\phi(t)dt \tag{59}$$

and $\frac{d^2}{dt^2}(iH)$ is represented in mass space by

$$\begin{aligned}\int_{-\infty}^{\infty}iH\phi''(t)dt&=\int_0^{\infty}(C_1+C_2\sin\omega t+C_3\cos\omega t)\phi''(t)dt\\&=-(C_1+C_3)\phi'(0)-\int_0^{\infty}\omega(C_2\cos\omega t-C_3\sin\omega t)\phi'(t)dt\\&=-(C_1+C_3)\phi'(0)+\omega C_2\phi(0)-\int_0^{\infty}\omega^2\times(C_2\sin\omega t+C_3\cos\omega t)\phi(t)dt\end{aligned} \tag{60}$$

where, in the second line, the coefficient of $\phi'(0)$ is the value of $(C_1+C_2\sin\omega t+C_3\cos\omega t)$ at $t=0$, and in the third line, the coefficient of $\phi(0)$ is the value of $(C_2\cos\omega t-C_3\sin\omega t)$ when $t=0$.

Since, as we have already pointed out, d^2H/dt^2 "does not exist as a function," we are in difficulty with the right-hand side of equation 50. However, we may choose to recognize it as the second derivative of the unit function, and although "it does not exist as a function," its representation in mass space does exist and is equal to

$$\int_{-\infty}^{\infty}H\phi''(t)dt=\int_0^{\infty}\phi''(t)dt=-\phi'(0) \tag{61}$$

Now substitute the mass representations given by equations 59, 60, and 61 in the differential equation 50 and obtain

$$-(C_1+C_3)\phi'(0)+\omega C_2\phi(0)-\int_0^{\infty}\omega^2(C_2\sin\omega t+C_3\cos\omega t)\phi(t)dt+\int_0^{\infty}\omega^2(C_1+C_2\sin\omega t+C_3\cos\omega t)\phi(t)dt=-\phi'(0) \tag{62}$$

In this equation we equate the parts under the integral sign and the coefficients* of $\phi(0)$ and $\phi'(0)$ on each side of the equation and obtain

$$\omega^2C_1=0 \tag{63}$$

$$\omega C_2=0 \tag{64}$$

and

$$C_1+C_3=1 \tag{65}$$

Hence

$$C_3=1 \tag{66}$$

as in equation 57 and, substituting in equation 51, we obtain

$$iH=\cos\omega tH \tag{67}$$

as in equation 58.

Application to an nth-Order Differential Equation

We may apply the above method to an nth-order equation

$$\sum_n a_n\frac{d^n}{dt^n}(iH)=EH \tag{68}$$

and assume a solution for it of the form

$$iH=\left(C_0+\sum_n C_n\epsilon^{-\alpha_nt}\right)H \tag{69}$$

where the α_n are determined in the usual manner. Substituting this in equation 68 we obtain $n+1$ equations by equating the coefficients of $H', H'', \ldots .H^{(n)}$ on each side of the equation, and from these the unknown constants can be determined. The difficulties associated with the use of $H', H'', \ldots .H^{(n)}$ can be avoided, of course, by using the Schwartz transformation method.

---

* The reason for equating the coefficients of $\phi(0)$ and $\phi'(0)$ separately is that $\phi(0)$ corresponds to a unit mass at $t=0$ and $\phi'(0)$ corresponds to a doublet at $t=0$.

This becomes a lengthy operation when n even exceeds two, and would involve an infinite set of equations when $n=\infty$, as it does in the solution of partial differential equations. The Heaviside expansion theorem is a very skillful way of getting around this difficulty, as we shall show now.

It has been seen that the values of the unknown constants in equations 28 or 36 can be obtained directly from the differential equations 27 or 35, and that no other assumptions have to be made in order to solve it. Since the information given in equations 27 or 35 by the introduction of H ensures that it has one and only one solution, we can assign a meaning to the equation when written in the form

$$iH=\frac{E}{L\frac{d}{dt}+R}H \tag{70}$$

To evaluate this expression for i, we simply rearrange in the form of equations 27 or 35 and solve this differential equation as shown and arrive at the solution in equations 34 or 44. From this we can write

$$\frac{E}{L\frac{d}{dt}+R}H=E(1-\epsilon^{-Rt/L})H/R \tag{71}$$

We may add n such terms together and get

$$\sum_n \frac{E}{L_n\frac{d}{dt}+R_n}H=\sum_n E(1-\epsilon^{-R_nt/L_n})H/R_n \tag{72}$$

We may add all the quantities on the left-hand side of this equation to get the quotient of two operators acting on H which we may write

$$\frac{\sum_n b_{n-1}\frac{d^{n-1}}{dt^{n-1}}}{\sum_n a_n\frac{d}{dt^n}}EH=\sum_n \frac{E}{L_n\frac{d}{dt}+R_n}H$$
$$=\sum_n E(1-\epsilon^{-R_nt/L_n})H/R_n \tag{73}$$

These three steps, in the order shown, are equivalent in reverse order to those used by Heaviside in the development of his expansion theorem. Using his terminology, replacing d/dt by p, he wrote[3]

$$iH=\frac{Y(p)}{Z(p)}EH=\sum_n \frac{Y(p_n)}{\left[p\frac{dZ}{dp}\right]_{p=p_n}}\frac{1}{p-p_n}H$$
$$=\frac{Y(0)}{Z(0)}H+\sum_n \frac{Y(p_n)\epsilon^{p_nt}}{\left[p\frac{dZ}{dp}\right]_{p=p_n}}H \tag{74}$$

Thus, by expanding in partial fractions we break the solution of a differential equation of the nth order up into the solution of n equations of the first order, whose solution has been found already in equations 34 and 44, and thus we avoid writing a general solution for the nth degree equation and then finding the values of $n+1$ constants in equation 69.

Application to Differential Equations of Infinite Order and Partial Differential Equations

This idea can be extended to differential equations of infinite order such as, for instance, a typical form shown by[4]

$$vH=\frac{\sinh\,(l-x)\sqrt{RS\frac{d}{dt}}}{\sinh\,l\sqrt{RS\frac{d}{dt}}}EH$$
$$=E\left(1-\frac{x}{l}\right)H-\frac{2E}{\pi}\times$$
$$\sum_{n=1}^{n=\infty}\frac{\sin\frac{n\pi x}{l}\epsilon^{-(n^2\pi^2t/RSl^2)}H}{n} \tag{75}$$

Such differential equations of infinite order arise naturally in one method of solution of the partial differential equations of mathematical physics. The introduction of H gives directly the coefficients of the functions in the resulting Fourier series or integrals, without the necessity of assuming a series with an infinite number of unknown constants and later determining these constants by methods similar to those involved in the use of Fourier's theorem. An extensive application employing this method will be found in a paper by one of the authors.[5]

In that paper are derived solutions of the differential equations of mathematical physics corresponding to Poisson's equation, the equation of heat conduction, Maxwell's wave equation, and the wave equation in a dissipative medium. These solutions are given in generalized orthogonal co-ordinates. To use them for a particular problem, it is only necessary to substitute in them the appropriate function, sine or cosine, or the Bessel functions, or the Legendre functions, and so forth, to get the final solution, which has checked in all cases tried with that given in the literature. Tables of such solutions for Green's functions for rectangular co-ordinates were presented at the AIEE winter meeting in 1949.

The method used in the Journal of the Franklin Institute paper[5] is based directly on the use of the impulse function where necessary, since the Schwartz method was not available at that time. It will be found that the use of the impulse function can be avoided by using the Schwartz method, which will lead to the same results given in that paper. Since this application of the Schwartz method is relatively easy, we refer the reader to that paper for more details as to the method of application to partial differential equations.

Application of Method to Given Initial Conditions

Since sometimes it is stated that the Heaviside method cannot be applied to problems where given initial conditions have to be met, it may be well to point out that this is not so and to indicate how such problems can be solved. Many such examples will be found worked out in chapter one of Jeffreys' book[7] using a different notation. To use it in the case of the simple example already discussed, we reformulate the problem stated on page 7 of reference 7 as follows:

> A voltage E is applied at the time $t=0$ to a circuit containing resistance R and inductance L in series. The current in the circuit is zero when $t<0$. At $t=0+\epsilon$ the current is i_0. Find the current when $t>0$.

We can write as before

$$L\frac{d}{dt}(iH)+RiH=EH \tag{76}$$

when $t<0$ and $t>0$. It must be noted that we now restrict the validity of this equation to the region $t<0$ and $t>0$, since the introduction of the terminal condition $i=i_0$ when $t=0+\epsilon$ means that it cannot hold at $t=0$. To introduce the terminal condition $i=i_0$ when $t=0+\epsilon$, integrate from $-\infty$ to t and obtain

$$LiH+R\int_0^t iHd\ =EtH+Li_0H \tag{77}$$

when $-\infty<t<\infty$. Then this equation incorporates all the given conditions of the problem and is valid from $-\infty$ to ∞.

Either the Heaviside or the Schwartz method can be used to solve it along the lines given in the previous example. In both of these methods we start with the solution in equation 28 and substitute in the integro-differential equation 77. It then will be found that by differentiating once, the equation reduces to one involving H and H' in the Heaviside method, and we obtain the values of the constants C_1 and C_2 as before, subject, of course, to the difficulties inherent in the use of H'. In the Schwartz method we get a representation in mass space consisting of two terms, one being an integral from $-\infty$ to ∞ and the other involving $\phi(0)$. By equating the coefficients of these two terms as before, we get the required result

$$iH=\frac{E}{R}(1-\epsilon^{-Rt/L})H+i_0H\epsilon^{-Rt/L} \tag{78}$$

It may be well to point out that in the Heaviside manner we find by differentiating equation 77 that this is the solution of

$$L\frac{d}{dt}(iH)+RiH=EH+Li_0H' \tag{79}$$

when $-\infty<t<\infty$. Thus equation 76 requires the addition of an impulse-function term to make it valid from $-\infty$ to ∞. Furthermore, equation 78 is the only solution of equation 79, just as equation 46 is the only solution of equation 45. There is no conflict between these statements.

Conclusion

In the paper we have emphasized the use of two concepts—the introduction of the Heaviside unit function to ensure that a given expression has the value zero in some parts of the region in which it is defined; the use of the impulse function and its derivatives which arise when we attempt to differentiate the unit function. These seem to the authors to be the ideas which make the operational methods used by Heaviside and others give the results they do.

Some difficulties are encountered in proceeding in this manner, due to the fact that the impulse function and its derivatives are not functions in the accepted mathematical sense of the word. The method of Schwartz is introduced; this permits us to take practically identical steps with those taken in the Heaviside approach. However, since the operations are carried out in mass space, no infinities are encountered and the results are put on a sound mathematical basis.

Some authors view the operational calculus as a method based upon substituting p for d/dt and then treating p as if it were a number. The point of view presented here considers that the substitution of p for d/dt is just a convenience in writing, and in order to emphasize this, no use has been made of p in this paper.

We have endeavored to focus attention on the other concept used by Heaviside, his unit function 1, for which we have used the symbol H. It is, perhaps, unfortunate that Heaviside, after explaining his unit function and its use, then decided that for brevity's sake he would omit it from the equations. If he had written it in the equations continually, its presence would have aroused curiosity, and its importance would have been better understood. In this paper we have tried carefully to be sure that in all the equations where a function of d/dt arises, it acts on an operand which is multiplied by H. If any are found which do not conform to this pattern they are oversights.

Other authors approach the operational calculus from the point of view of the Laplace transformation. In a certain sense the Schwartz method may be regarded as a generalization of the Laplace transform

$$\int_0^\infty \epsilon^{-ax}f(x)dx$$

in which the function $\phi(t)$ replaces the exponential factor and the limits of integration are extended throughout the range of the function $\phi(t)$ rather than from zero to infinity. It goes much further than this, however, as it gives us a method of interpreting the derivative of any order of a discontinuous function. Furthermore, on account of the general character of $\phi(t)$, it can be used with many types of functions—Bessel, Legendre functions, and so forth, and their associated differential equations; whereas the Laplace transform is intimately tied in to the exponential function and its associated linear differential equation with constant coefficients of the first degree and nth order.

By the introduction of H we obtain a system in which integral and differential operations are reversible. This comes about due to the fact that when H is suitably introduced into the differential equations and the differential and integral operations are performed, there results an equation of the form

$$\sum_{n=0}^{n=p}a_n\frac{d^nH}{dt^n}=\sum_{n=0}^{n=p}b_n\frac{d^nH}{dt^n} \tag{80}$$

in the Heaviside method or an equation of the form

$$a_0\int_{-\infty}^{\infty}f(t)\phi(t)dt+\sum_{n=1}^{n=p}a_n\phi^{(n-1)}(0)$$
$$=b_0\int_{-\infty}^{\infty}f(t)\phi(t)dt+\sum_{n=1}^{n=p}b_n\phi^{(n-1)}(0) \tag{81}$$

in the Schwartz method.

From this we can conclude that the coefficients of the nth derivative of H on each side of the equation are equal in the Heaviside method, while in the Schwartz method $a_0=b_0$ and the coefficients of $\phi^n(0)$ on each side of the equation are equal, so that

$$a_0=b_0$$
$$a_1=b_1$$
$$\cdots\cdots$$
$$a_n=b_n \tag{82}$$

This is quite analogous to the case of the complex variable where if x,y,a, and b are real and we are given

$$x+iy=a+ib \tag{83}$$

we can conclude that

$$x=a,\ y=b \tag{84}$$

The methods in this paper follow very closely the ideas expressed by Heaviside in the following quotation,[6] which seems an appropriate one with which to conclude:

> "It may be remembered that I have insisted on the definiteness and fullness of the meaning of an operational solution, and that it contains within itself not only the full statement of the problem, but also its solution. No external aid is therefore required to algebrise it fully; no assumption, for instance, of a special type of solution and that the solution is the sum of a number of that type with subsequent determination of the constants required to complete the matter. The work of satisfying the imposed conditions has been done already."

Discussion

P. A. Abetti (General Electric Company, Pittsfield, Mass): The authors are to be commended for their derivation of Heaviside's operational calculus which, among the many attempted so far, is mathematically rigorous, physically simple, and closely related throughout to Heaviside's own work. In fact, if we consider the simple applications to first and second order differential equations, we find a complete equivalence of every step of the Schwartz method with every step of the Heaviside method. For instance, in the section in the paper on second order differential equations, the following equations are equivalent: 59 to 51; 60 to 53; 62 to 54; 63 to 55; 64 to 56; 66 to 57; 67 to 58.

It will be recognized, however, that the equations 51 to 54 are simpler in form and easier to manipulate than equations 59 to 62, which contain infinite integrals and the minus signs introduced by equation 17. On the other hand, the Schwartz transformation equations are mathematically rigorous in the mass space, while the derivatives H', H'' of the unit function "do not exist" mathematically at the point of discontinuity and are zero elsewhere, so that the legitimacy of equations 50 to 54 is extremely doubtful.

It appears that a compromise between the rigorousness of the Schwartz method and the simplicity and elegance of the Heaviside would be very useful, especially for those who are concerned with the operational methods as working tools. Such a compromise may be obtained easily by writing all steps of the solution in the Heaviside manner, but adding a special symbol, say Ⓜ or Ⓢ, whenever derivatives of the unit function appear, to indicate that the operations take place in the mass space, or in the field of the Schwartz transform, and are therefore rigorous and legitimate.

Mr. Alger and Mr. Smith also must be commended, for psychological reasons, for having written d/dt instead of p everywhere in their paper. In fact, let us consider the reactions of the layman, practical engineer or student, to the introduction of the operational calculus in his daily work, as specified by Angelini.[1]

1. Some find the operational calculus very useful in its application to practical problems, especially in the electrical field.

2. Others do not believe that it is worthwhile to employ operational methods, either because they find no occasion in which these might be useful, or else because such occasions appear so seldom in their work that they consider the effort necessary to learn these new methods of calculation out of proportion with the limited use they would have for them.

3. Others finally are disappointed and puzzled by the many different aspects under which the operational calculus is presented to them, by the lack of mathematical rigour and ensuing pitfalls of some methods, and sometimes by the opinion of some mathematicians on the subject. They renounce therefore to learn and to employ the operational methods and make use, whenever necessary, of the classical methods of analysis.

Concentrating our attention to the last group, and eventually also to the second, and especially to those who have not yet formed their opinion on the subject, the operational methods may be presented to all these groups with emphasis on either one of the following two points wherein they basically differ from the classical ones:

1. The completeness of the solution which incorporates the initial conditions and eliminates the integration constants of the classical methods.

2. The "symbolic" property of writing p (or any other letter) for the operator d/dt, and treating this symbol as any other algebraic quantity.

Any person who has used the classical methods and wrangled with the calculations of several integration constants, will appreciate the great advantages of point 1 above. Very few engineers or students instead, are favorably impressed with point 2 as such, wherein they see no practical advantages for their work, and which they sometimes distrust as "illegitimate" from the standpoint of mathematical rigour. K. W. Wagner[2] attributes to this reason the fact that the first rigorous approach to operational methods contained in two very remarkable papers[3,4] written by Giorgi as far back as 1904–05, has found such poor reception among engineers.

The only point in the paper Messrs. Alger and Smith wrote which might draw the suspicion of the layman is the appearance of the symbol $\sqrt{RSd/dt}$ in equation 76. However, the introduction of fractional differentiation and integration, as Riemann[5] defined it in 1876, will clear these difficulties and we look forward to the announced paper on this subject.

Giorgi also first realized the great importance of the impulse function, which now, together with its derivatives, finds a legitimate place in the mass space through the transformation of Schwartz.

In view of the fact that the work of Giorgi is little known in this country and was not even quoted among the 84 references of a recent paper[6] on the history of the operational calculus, its accomplishments will be reviewed here.

On the basis of the work of Pincherle[7] and other mathematicians on the properties of distributive operations, Giorgi justifies the application of the algebraic rules to the operator $d/dt = \Delta$ and establishes the limits of their validity.

The operational expression of Giorgi is

$$i(t) = \psi(\Delta)v(t) \tag{1}$$

in which the operator is a function, eventually irrational, of the symbol Δ and $v(t)$ is a "physical" function, that is, which satisfies Dirichlet's conditions. Giorgi interprets equation 1 by resolving the function $v(t)$ in its frequency components by the Fourier integral, applying to each component the operator, and obtains the results by superposition. We arrive thus at a general formula, called "Giorgi's integral," for the evaluation of operational expressions.

For practical applications, instead of using Heaviside's and Carson's "indicial admittance," the response to a unit step function H, Giorgi employs the response to a unit impulse function ΔH, that is, Green's function $g(t)$

$$g(t) = \psi(\Delta)\Delta H \tag{2}$$

The response to the function $v(t)$ is obtained as the sum of the responses to an infinite number of impulse functions in which $v(t)$ has been resolved

$$\psi(\Delta)v(t) = \int_{-\tau}^{+\infty} g(t-\tau)v(\tau)d\tau \tag{3}$$

Changing the variable from $(t - \tau)$ to θ in equation 3 we obtain the equivalent expression

$$\psi(\Delta)v(t) = \int_0^\infty g(\theta v(t-\theta)d\theta \tag{4}$$

Giorgi has proved, even for discontinuous functions, the relation

$$\epsilon^{h\Delta}v(t) = v(t+h) \tag{5}$$

so that equation (4) may be written as

$$\psi(\Delta)v(t) = \int_0^\infty g(\theta)\epsilon^{-\theta\Delta}v(t)d\theta \tag{6}$$

Wherefrom, since equation 6 is valid for any $v(t)$, we obtain

$$\psi(\Delta) = \int_0^\infty g(\theta)\epsilon^{-\theta\Delta}d\theta \tag{7}$$

Under certain conditions, equation 7 expresses the fact that Green's function $g(\theta)$ is the inverse Laplace transform of the operator $\psi(\Delta)$. If instead of Green's function, we write the initial admittance $A(\theta)$ in equation 7 we obtain, since $g(\theta) = \Delta A(\theta)$

$$\frac{1}{\Delta}\psi(\Delta) = \int_0^\infty A(\theta)\epsilon^{-\theta\Delta}d\theta \tag{8}$$

which is the same as the integral used by Carson (1922–26) as the foundation of his approach to operational calculus.

If we consider that these relations which correlate the principal methods of the operational calculus, were obtained as far back as 1905, seven years before Heaviside himself finished his great work and 11 before the appearance of Wagner's and Bronwich's justification of Heaviside's work, we must conclude that Giorgi's work deserves more recognition and study than it has been granted in the past 45 years.

J. J. Smith and **P. L. Alger**: We thank Mr. Abetti for bringing out clearly the equivalence between the equations using the Schwartz method and the Heaviside method.

In writing the paper we started out with the idea of using only the Schwartz method but it became apparent that if this method alone were used the paper would not be easy for engineers accustomed to the Heaviside method to understand. We therefore adopted the compromise of using both the Heaviside method and the Schwartz method on the same problems, so it is hoped the equivalence between the steps in both methods is apparent from this procedure.

While the Schwartz method is simple to use when one is accustomed to it and is more rigorous, nevertheless, it does entail considerably longer expressions than those involved in the Heaviside method. Here, Mr. Abetti makes a good suggestion. He says, why not write, for instance, equation 29 as follows:

$$(C+C_1\epsilon^{-Rt/L})LH'+CRH=EH \qquad Ⓜ \quad (29)$$

$$\text{or} \qquad Ⓢ \quad (29)$$

where the symbol before the number of the equation means (1) the mass space equivalent Ⓜ or (2) the equivalent representation of Schwartz Ⓢ is to be understood. This equation can be translated into the Schwartz terminology by noting that since H' is zero everywhere except when $t=0$, the equation can be written putting $t=0$ in the exponential

$$(C+C_1)LH'+CRH=EH$$

and the mass space representation of this equation is then given by

$$L(C+C_1)\phi(0)+CR\int_{-\infty}^{\infty}H\phi(t)dt=$$

$$E\int_{-\infty}^{\infty}H\phi(t)dt$$

which is equation 41.

In the more general case of the nth order derivative, we have

$$\frac{d^n}{dt^n}(f(t)H)=\sum_{p=0}^{p=n}f^{(p)}(0)H^{(n-p)}$$

in the Heaviside method. Whereas in the Schwartz method taking the representation of $f(t)\ H$ in mass space we have

$$\int_{-\infty}^{\infty}\frac{d^n}{dt^n}\{f(t)H\}\phi(t)dt$$

$$=(-1)^n\int_{-\infty}^{\infty}f(t)H\phi^{(n)}(t)dt$$

$$=(-1)^n\int_{0}^{\infty}f(t)\phi^{(n)}(t)dt$$

$$=\int_{0}^{\infty}f^{(n)}(t)dt+\sum_{p=1}^{p=n}(-1)^{p-1}f^{(p)}(0)$$

$$\phi^{(n-p)}(0) \qquad (9)$$

By comparing these two formulas, any equation written in the Heaviside notation can be rewritten readily in the Schwartz notation by replacing

$f(t)H$ by $\int_{-\infty}^{\infty}f(t)H\phi(t)dt$

$f(0)H'$ by $f(0)\phi(0)$

$f(0)H^{(n)}$ by $(-1)^{n-1}f(0)\phi^{(n)}(0)$

With regard to the symbol $\sqrt{RSd/dt}$ in equation 75, it will be noted that both the numerator and denominator are odd functions of $\sqrt{RSd/dt}$ and thus this term cancels out leaving functions of RSd/dt so that no fractional differentiation is involved in this particular example. However, as mentioned in a footnote, we shall discuss fractional differentiation in a subsequent paper.

With regard to Mr. Abetti's reference to Giorgi's work, there is much to be said in favor of using the response of a system to a unit impulse, rather than the response to a unit function (indicial impedance). The resulting expressions are often much simpler and more symmetrical and in many cases can almost be written down on sight. A close examination of the superposition theorem will show that the differentiation involved in it is really used to derive the response to an impulse function from the indicial impedance and the subsequent integration corresponds to the summation of the effects of a large number of such impulse functions to simulate the given function whose reaction it is required to determine. Of course, the main objection to its use up to now has been the "nonexistence" of the impulse function in the mathematical sense. The introduction of the Schwartz method should rectify this and justify the very elegant derivation of the Laplace integral given by Mr. Abetti. We have given an even simpler derivation in a paper just completed basing it similarly on the properties of the unit function and its derivative.

In connection with this nonexistence in the mathematical sense of H', $H^{(n)}$, and so forth, and which also leads Mr. Abetti to point out "the legitimacy of equations 50 to 54 is extremely doubtful," there may be a possibility of handling such entities in the Heaviside manner without resorting to the Schwartz method. This involves consideration in the Stieltjes manner of the differentials dH, $d^2H, \ldots d^nH$ which exist, rather than the derivatives H', H'', $\ldots$ $H^{(n)}$ which do not exist. It is, perhaps, premature to raise hopes in this respect, although the authors hope to write up some ideas on this in the near future. In the meantime, it might be well if students of engineering were introduced to Stieltjes integrals and functionals so as to be able to study Heaviside's work from these points of view.

Heating of Transformers Under Short-Circuit Conditions

V. M. MONTSINGER
MEMBER AIEE

G. H. HALSEY
ASSOCIATE AIEE

THIS PAPER discusses the effect of turn insulation on the temperature rise and the relative aging of this insulation during the heating and cooling periods. It is shown: that the absorption of heat by the insulation cannot be neglected in accurate calculation of temperature rise; that most of the aging occurs during the cooling period; and that the allowable temperature limit should depend upon the rate of cooling.

This paper gives a formula for calculating temperature rise that allows for the effect of insulation. This formula is easier to use than those given in the ASA C57 Standards for Transformers, Regulators and Reactors.[1] It is pointed out that the present formulas in the standards are cumbersome to use and do not factor the absorption of heat by turn insulation. It is also pointed out that additional work is necessary before any revision of the ASA standards can be undertaken.

General Considerations

For many years, the AIEE transformer standards, and, in more recent years the ASA standards, have specified that short-circuit temperature rises be calculated without allowing for heat storage capacity of the winding insulation. Furthermore, while the standards have made no definite statement about it, it has been the general understanding that the duration of the short-circuit and the ultimate temperature reached are the most important factors to be considered in determining the life of the insulation.

When a short circuit is applied to a winding, all the heat is stored in the copper at the very beginning. As the temperature increases, heat is transferred to the insulation and later to the oil adjacent to the insulation. The insulation may comprise both turn-to-turn and layer-to-layer insulation.

The maximum temperature that is important is that temperature existing in the insulation when the aging starts to be a measurable amount. This is illustrated in Figure 1, in which it is assumed that the temperature of the copper reaches 250 degrees centigrade before any heat is absorbed by the insulation, at which time the short circuit is removed. The cooling takes place in two stages: firstly, the conductor insulation absorbs its share of the heat very rapidly, reducing the temperature of the copper to, say, 220 degrees centigrade in three to five seconds. Secondly, the cooling from this point on takes place by dissipation of the heat to the oil at a relatively slow rate, in terms of minutes instead of seconds, during which time most of the aging takes place. For practical purposes then, the temperature during the slow-cooling period is far more important than the maximum copper temperature attained up to the time when the slow rate of cooling starts in.

The ASA Standards C57.12.050-.051[2] have two limitations under short circuit. One limitation (mechanical) is that the magnitude of the symmetrical current must not exceed 25 times normal current. The other limitation (thermal) is that the maximum copper temperature must not exceed 250 degrees centigrade when using class *A* insulation.

This paper is concerned only with the thermal limitation for transformers using class *A* insulation. The authors will show:

1. That turn-to-turn insulation should be factored when calculating the storage of heat in transformer windings.

2. That, for a given maximum temperature, the aging of the insulation resulting from a short circuit depends on the rate of cooling rather than on the duration of the short circuit.

3. That, to produce the same thermal effect, the maximum temperature should vary with the rate of cooling.

Tests to Determine Temperatures During Heating and Cooling Cycle

To obtain heating and cooling data, many tests were made on transformer windings of the disk-coil type having three sizes of conductors with different amounts of turn insulation, as shown in Table I.

The tests were made with the coils in both horizontal and vertical positions and in oil at temperatures ranging from 24 to 75 degrees centigrade. These tests provided two kinds of data: firstly, a comparison of the tested and calculated rises (based on all heat stored in the copper) during the heating period; and secondly, the thermal capacity of the turn insulation that applied during both the heating and cooling periods, under loads ranging from moderate overloads (run until conditions became constant) to short-circuit conditions until temperature rises as high as 200 degrees centigrade were reached.

HEATING PERIOD

Paper 49-189, recommended by the AIEE Transformer Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer General Meeting, Swampscott, Mass., June 20-24, 1949. Manuscript submitted March 14, 1949; made available for printing May 5, 1949.

V. M. MONTSINGER and G. H. HALSEY are with the General Electric Company, Pittsfield, Mass.

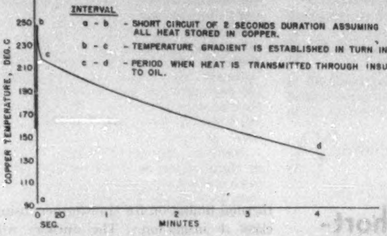

Figure 1 (above). Heating and cooling of typical oil-immersed transformer winding when subjected to short-circuit

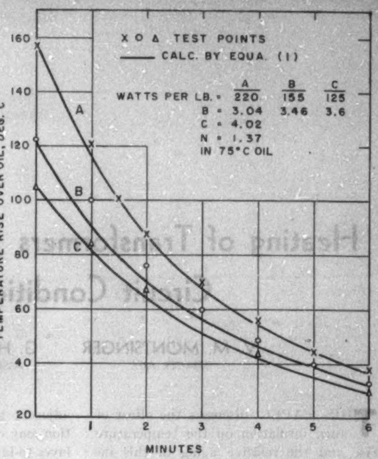

Figure 3 (right). Cooling curves of winding having conductor 0.450 by 0.075 inch, *P.024-C.007*, two sides, insulation

tion shows curves of tested and calculated temperature rises during 40-second short circuits when 400, 500, and 550 amperes were forced through the 0.450- by 0.075-inch conductor with *P.024-C.007* insulation in 30-degree-centigrade oil. It will be noted that the solid lines representing the test values fall below the dashed lines representing the calculated values assuming all the heat stored in the copper. For example, at the end of ten seconds duration, the percentage of generated heat that remained in the copper was as shown in Table II.

Results of similar tests reported in Figures 1 and 2 of reference 4, made on 0.435- by 0.095-inch *P.012-C.007* insulated conductor, are seen in Table III.

It appears safe to assume that at least 20 per cent of the total heat generated will always be stored in the insulation of an average winding.

COOLING PERIOD

Figures 3 and 4 show a comparison of tested and calculated cooling of windings having 0.450- by 0.075-inch *P.024-C.007* conductors in which the temperature rise at the start of the cooling ranges from approximately 100 to 200 degrees centigrade. The cooling was calculated by the following equation

$$\theta=\theta_0\left[1+(n-1)\frac{T}{\tau}\right]^{\frac{-n}{n-1}} \tag{1}$$

where

θ = temperature rise of winding, degrees centigrade, at any time, T
θ_0 = temperature rise of winding at start of cooling period
n = exponential power of ultimate temperature rise (θ_0^n) versus loss
T = time after start of cooling—minutes
$\tau=\frac{\theta_0 C}{W_0}$
C = specific heat of copper plus insulation
W_0 = watts per pound necessary to maintain a steady-state temperature rise of θ_0

After the current density of the copper to maintain the temperature rise, θ_0, is determined, W_0 can be calculated from

$$W_0=KD^2 10^{-6}$$

where

K = 2.16 for copper at 25 degrees centigrade
D = amperes per square inch

Based on the limited data available, the authors have used for several years the thermal capacity of turn insulation by volume as one-half that of copper, that is

$$C=2.96+1.48\frac{A_i}{A_c} \tag{2}$$

where

A_i = cross section of insulation
A_c = cross section of copper

The value of 2.96 for copper corresponds to a specific heat of 0.0935 calorie per gram per degree centigrade. As the specific heat of copper increases slightly with temperatures, the value of 3.04, instead of 2.96, was used in AIEE Standards Number 32.[3] Also, when the Standards for Neutral Grounding Devices, were under preparation, the data at that time indicated that "by volume" the thermal capacity of turn insulation was 86 per cent that of copper. That is,

$$C=3.04+2.62\frac{A_i}{A_c} \tag{3}$$

A thorough study of all tests made on the three different amounts of turn insulation previously mentioned, including both the heating and cooling cycles, indicates that the thermal capacity of turn insulation is by volume approximately 67 per cent (or 2 A_i/A_c) that of copper.

Rounding out the 2.96 and 3.04 values to 3.00 which is easily remembered, the equation which best fits the test results is

$$C=3.00+2.0\frac{A_i}{A_c} \tag{4}$$

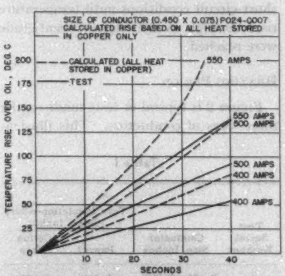

Figure 2. Tested and calculated temperature rises during 40-second duration in 30-degree-centigrade oil

Table II

Amperes	Per Cent Heat Retained in Copper in First Ten Seconds
400	65
500	78
550	80

Amperes	Per Cent Heat Retained in Copper in First Ten Seconds	
	Figure 1	Figure 2
400	70	60
500	70	72
550	68(500 amperes)	70

which allows 67 per cent "by volume" for the turn insulation. See Table IV for comparison of tested and calculated values of temperature rises using equations 3 and 4.

According to equation 1, the rate of cooling is determined largely by the time constant which ranges from approximately 3 to 15 minutes for most transformer windings at normal operating temperatures. When windings attain short-circuit temperatures, the time constant is reduced, since the steady-state temperature rise does not vary directly with the loss. For example, equation 8 of Appendix II of ASA C57.32[1] states that the time constant varies as the 0.25 power of the ratio of the temperature rise at rated load to any higher rise. That is, if the coil rise over oil at rated load is 20 degrees centigrade when the rise over oil under short circuit reaches (250 degrees–75 degrees oil temperature =) 175 degrees centigrade, the time constant will be decreased to $(20/175)^{0.25} = 0.58$ of that at 20 degrees centigrade rise. Therefore, time constant of 15 minutes at rated load will be 15 by 0.58 = 8.7 minutes, or approximately one-half that at rated load.

Aging of Insulation During Heating and Cooling Periods

Now, having discussed both the heating and cooling during a short-circuit cycle, we can now determine what percentage of the total aging takes place during the heating cycle.

As shown previously,[5] the aging of insulation during an abrupt rise in temperature and slow cooling can be calculated by integrating the area of the heating and cooling curve either by using the equation

$$A = te^{XT_2} \qquad (5)$$

where

A = aging units
t = time expressed in seconds, minutes, or hours
X = constant (0.0865 when the aging doubles for each 8 degrees centigrade increase in temperature)
T_2 = maximum temperature, degrees centigrade

or, by forming a trapezoid the area of which is approximately the same as the temperature area, and using the equation

$$A = t\left[\frac{e^{XT_2} - e^{XT_1}}{X(T_2 - T_1)}\right] \qquad (6)$$

When $X = 0.0865$, equation 6 reduces to

$$A = t\left[\frac{\log_{10}^{-1}(0.0375\ T_2 - 0.0375\ T_1)}{0.0865\ (T_2 - T_1)}\right] \qquad (7)$$

where

T_2 = maximum temperature of trapezoid
T_1 = lower temperature of top line of trapezoid. The values of T_1 should be such that the aging is negligible for T_1 and lower values
t = time corresponding to length of top line of trapezoid

Figure 5 shows curves constructed of two heating periods of five and ten seconds, also, three cooling curves for windings having 2-, 4- and 8-minute time constants (at 250 degrees centigrade).

As the aging with which we are concerned here is the ratio of the aging during the heating period to the aging during the cooling period, time, t, can be expressed in any convenient units. Letting $T_2 = 175$ degrees centigrade and $T_1 = 100$ degrees centigrade for the 5-second heating period, t is approximately 2.1 seconds.

By equation 7

$$A = 2.1\left[\frac{\log_{10}^{-1}(0.0375 \times 175 - 0.0375 \times 100)}{0.0865(175 - 100)}\right] = 1.2 \times 10^6 \text{ units}$$

Since the heating curve is almost a straight line, the aging during the 10-second heating period is approximately 2.4 by 10^6 units.

Referring to Figure 5, it will be seen that the lapse of time from the point on the triangle *a b c*, when the coils having a time constant of two minutes reach 100-degree rise on the 5-second heating period and decrease to 100-degree rise on the cooling period, is 59 seconds. Experience has shown that the integration of triangle *a b c* gives approximately the same results as the integration by parts of the entire heating and cooling area *a b d*. The aging during this complete cycle can also be calculated by equation 7, that is

$$\text{Aging} = 59\left[\frac{3{,}630{,}000 - 5600}{0.0865(175 - 100)}\right] = 32.9 \times 10^6 \text{ units}$$

Therefore, the aging during the 5-second heating period is

$$\frac{1.2 \times 10^6 \times 100}{32.9 \times 10^6} = 3.65 \text{ per cent of the total aging}$$

The percentage of aging for coils with time constants greater than two minutes

will, of course, be less than 3.65 per cent because the cooling is at a slower rate.

Using the curves shown in Figure 5 and calculating the aging as illustrated, Table V shows the aging during the heating period in percent of total aging for coils having 2-, 4-, and 8-minute time constants and for 5- and 10-second heating periods.

From Table V, it is seen that for heating periods up to ten seconds practically all the aging under short-circuit conditions occurs during the cooling period, which depends on the time constant of the windings. From a thermal standpoint, the duration of a short-circuit of any reasonable period can therefore be neglected.

Method of Specifying Temperature Limits

When AIEE Standard Number 32 for Neutral Grounding Devices was under revision during 1946 and 1947 by the AIEE Subcommittee on Protective Devices (Mr. J. E. Clem, Chairman), it became evident from the data given in reference 4 that the temperature limits during a fault of one minute's duration or less should be a function of the rate of cooling after the fault had been removed rather than the length of time during the fault. This was especially true for transformers having a wide range of cooling rates and time constants. For example grounding transformers may have either well-ventilated coils and rapid cooling rates with normal time constants or they may have practically no cooling ducts resulting in very slow cooling rates and large time constants.

Table V

Coil Time Constant, Minutes	Aging During Heating Period in Per Cent of Total Aging, for Heating Periods of	
	Five Seconds	Ten Seconds
2	3.65	7.05
4	1.92	3.77
8	1.06	2.1

Based on these considerations, the subcommittee established a table of allowable temperature rises versus minimum cooling rates for the first minute as shown in Table VI taken from Table 32.11B of AIEE Standard Number 32.

So far as is known, this is the first time that the heating period has been disregarded and the permissible maximum temperatures based on rate of cooling.

While the time constants of power-transformer windings that carry continuous load do not vary over the wide range that applies to grounding transformers, the time constants and rates of cooling do vary sufficiently to justify establishment of a range of permissible temperature limits.

Variation of Temperature Limit with Time Constant

The following steps are made to see how the temperature limit may vary for different time constants to produce approximately the same aging during a short circuit.

Table VI

Time Constant, Minutes	Time, *t*, Seconds	Relative Aging
2	59	1.0
4	112	1.9
8	202	3.42

In Figure 5, the relative aging for all three time constants will be proportional to the time, *t*, since T_2 and T_1 have the same values for all three curves.

For the 5-second heating and three cooling periods, the aging is as in Table VI.

Based on the aging doubling for each eight degrees increase in temperature, to produce the same aging in the three coils would require: a difference of 7.5 degrees centigrade between coil number *1* and coil number *2;* and a difference of 14 degrees centigrade between coil number *1* and coil number *3.* For a coil having a time constant of 16 at 250 degrees centigrade, the temperature limit should be approximately 25 degrees centigrade less than for coil number *1.*

Based on these data, if we assume that 250 degrees centigrade is a safe maximum temperature for all windings having a time constant of two minutes or less the figures given in Table VIII can be drawn up.

The temperature limit under short-circuit conditions for power transformers has been 250 degrees for the past 30 or 40 years. As pointed out previously, this temperature has been based on all heat being stored in the copper only. There is good reason to believe that a temperature of 250 degrees is seldom if ever reached under short circuit; firstly, because some of the heat is stored in the conductor insulation; secondly, full voltage is not maintained under short-circuit unless the

101	3.8
93	1.9
85	0.9
77	0.5

Table VIII

Approximate Winding Time Constant in Minutes		Maximum Temperature to Produce Approximately Same Aging, Degrees Centigrade
At 250 Degrees Centigrade	At 95 Degrees Centigrade	
2 or less	3.5 or less	250
4	7.0	242.5
8	14.0	236
16	28.0	225

kilovolt-ampere capacity of the transformer in question is small in comparison with the source of power; and thirdly, the protective relay generally comes into action before the time limit is reached. If an allowance is made for the storage of heat in the conductor insulation, the question naturally arises as to whether 250 degrees is the proper value or should it be reduced to obtain approximately the same temperature as has been attained in the past. For example, if we assume that the temperature rise of the windings during short circuit is, say, 80 per cent of the calculated value based on all heat stored in copper only, this means that if the initial temperature is 95 degrees, the actual temperature attained would be (250–95) 0.8+95=219 degrees centigrade instead of 250 degrees centigrade.

Formula for Calculating Storage of Heat

Equations 22.105(a) and (b) given in the ASA Standards C57.22[1] do not include the effect of insulation in the storage of heat. Furthermore, these equations are cumbersome to use, especially 22.105(a).

The equation given in paragraph 32-3.11A of AIEE Standard Number 32 allows for storage of heat by the conductor insulation. This equation, however, expresses the copper loss in watts per pound instead of amperes per square inch which term is more convenient to use. With zero eddy loss and when expressed in amperes per square inch this equation reduces to

$$\theta=T_0\left[\log_{10}^{-1}\left(\frac{6D^2t10^{-11}}{C}\right)-1\right] \qquad (8)$$

where

θ = temperature rise in degrees centigrade
T_0 = starting temperature absolute $(234.5+\theta_0)$
θ_0 = starting temperature in degrees centigrade
D = amperes per square inch
t = time in seconds
C = specific heat of copper plus insulation
$C=3.00+2.0\frac{A_t}{A_c}$
A_t = cross section of turn insulation
A_c = cross section of copper conductor

In equation 32–3.11A of AIEE Standard Number 32 the eddy loss is lumped in with the I^2R loss watts per pound. This assumes that the eddy loss varies directly with the absolute temperature the same as I^2R varies.

In ASA equation 22.105(b), the eddy loss varies inversely with the absolute temperature.

If an empirical eddy-loss factor is put in equation 8, very good agreement is obtained with ASA equation 22.105(b) over a wide range of amperes per square inch and per cent eddy loss. With an eddy-loss factor introduced, equation 8 becomes

$$\theta=T_0\left[\log_{10}^{-1}\left(\frac{6D^2Et10^{-11}}{C}\right)-1\right] \qquad (9)$$

where

$E=\left(1+\frac{e}{100}\right)^{0.8}$
e = eddy loss in per cent of I^2R at 75 degrees centigrade

Table IX. Comparison of Results

Initial Temperature = 95 Degrees Centigrade

* Using $C=2.96$ instead of 3.04 for copper only.

Table IX gives a comparison of the results obtained by three equations to show the effect of eddy loss without factoring the turn insulation:

1. 32–3.11A from AIEE Standards Number 32.
2. Equation 9 in paper.
3. 22.105(b) from ASA Standard C57.22.

A comparison of the values shown in Table IX shows:

1. With zero eddy loss, the three equations give the same results.
2. With eddy loss present and for temperatures up to 250 degrees centigrade, the values calculated by equation 9 give results quite close to those given by ASA equation 22.105(b).

Since equation 9 is easy to use, it is recommended that it replace ASA equation 22.105(a) which is cumbersome to use and does not allow for the absorption of heat by the insulation.

Effect on Transformer Design of Changing Short-Circuit Temperature Rules

The question naturally arises as to the effect on transformer design of changing the short-circuit temperature rules. The present limiting temperature of 250 degrees centigrade calculated on the basis of all heat stored in the copper is easily met in present-day designs, except in very rare cases. However, if the copper densities are increased as improved methods of cooling are developed or by other design requirements, more accurate calculation of temperatures resulting from short-circuit conditions may be required.

Future Work

The data presented in this paper were obtained on disk types of windings. Other factors which may materially affect the rate of cooling are additional insulations not present in disk windings, such as layer insulations between multiconductor layers and windings wound directly on cylinders. Future investigations also should determine the effect of storing heat in the oil flowing up through tall windings where the oil temperature may be increased greatly for an appreciable time before it leaves the coil stack following a short circuit.

While these factors will probably have a small effect on the storage of heat, they may have a decided effect on the rate of cooling. When these factors have been investigated and reported, the question of revising the ASA standards to put them on a more logical basis, should be considered by the AIEE Transformer Committee.

Discussion

V. V. Mason (The Hydro-Electric Power Commission of Ontario, Toronto, Ontario, Canada): For estimating the loss of life due to a short time overload the authors give their equation 5

$$A = Ie^{XT_2} \qquad (1)$$

For the more elevated temperature where the rate of loss of life doubles for each rise of 8 degrees centigrade, this formula holds, but only for constant T_2. For varying temperatures, the integral form must be used, namely

$$A = \int e^{XT} dt \qquad (2)$$

In the authors' equation 6, an approximation is made to the above integral by assuming that the cooling curve is a straight line. This approximation, gross as it may seem at first glance, is probably not so bad in most practical cases if cleverly made. However, it is sometimes difficult to decide just how clever an approximation one has made.

The purpose of this discussion is to introduce a new type of graph paper which we call "loss-of-life" paper. Use of this paper avoids the uncertainty attendant upon making the approximation used by the authors. This loss-of-life paper has a linear time scale and a nonlinear temperature scale, such that the distance along the Y-axis is proportional to the rate of loss of life. Thus the area under any curve representing a temperature cycle is proportional to the loss of life for that cycle.

An additional advantage which accrues from the use of this paper is that account may easily be taken of the fact that the rate of deterioration halves for smaller and smaller temperature decrements as the temperature falls towards 95 degrees centigrade. That is, we may take into account the nonlinearity of the curves of per cent loss of life versus hot-spot temperature when plotted on semilog paper as in Figure 4 of Appendix 1 of the American Standards for Transformers, Regulators, and Reactors. It was the rate of loss of life figures calculated from these American Standards Association curves which were used in the preparation of this special graph paper.

Figures 1 and 2 of this discussion show samples of this type of paper. Figure 1 is for moderate overloads going up to a maximum of 131 degrees centigrade, while Figure 2 is for more severe overloads going up to 183 degrees centigrade.

This loss-of-life paper not only avoids the approximations otherwise necessary but also makes the procedure almost entirely graphical. This is especially so if it is used in conjunction with the transient heating and cooling papers which have been described in previous literature.[1,2]

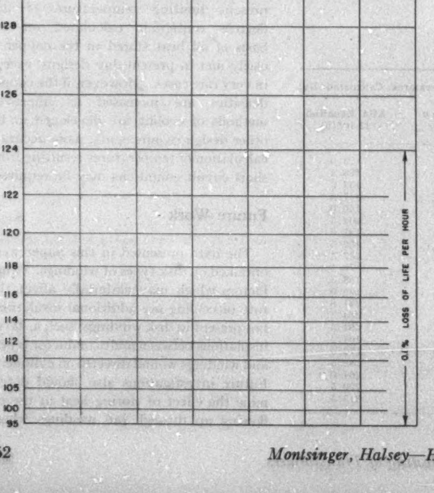

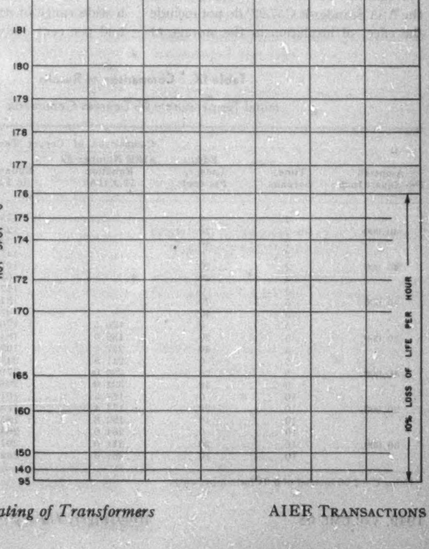

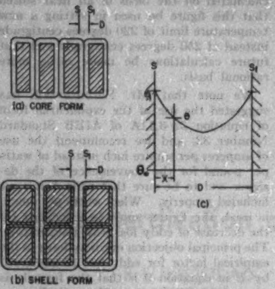

Figure 3. Arrangement of copper and insulation in core and shell form transformers

Paul Narbutovskih (Westinghouse Electric Corporation, Sharon, Pa.): In their paper the authors have brought up for consideration by industry and the utilities a subject which has been maturing for some time. The basic thesis—the relation of the permissible winding temperatures in transformers under very short time overloads to the duration of the cooling period rather than the heating period—is fundamentally sound, and has been recognized for a number of years, although until now it has not been proposed for inclusion into the industry standards for transformers. Our knowledge of the insulation life under exposure to high temperature is still imperfect. So long, however, as the available knowledge has been applied to the formulation of permissible overloads on transformers, it can be applied to the formulation of permissible practices for short circuit conditions. From this point of view the paper is undoubtedly a step in the right direction.

The inclusion of the thermal capacity of insulation into calculation of the windings temperature under short-circuit conditions is likewise entirely sound. The quantitative effect of the insulation, however, may merit further consideration, particularly in view of the fact that on Figure 2 of the paper the calculated temperature rise for 550 amperes appears to be erroneously too high. A correction of this curve will increase the per cent heat stored in copper to about 95 or 97 per cent instead of the 80 per cent quoted in the paper for the first 10 seconds. A further insight into the effect of the insulation upon the final temperature reached by the copper and the insulation can be gained by considering the diffusion of heat from copper into the insulation under transient conditions.

Consider Figure 3 of the discussion, which shows a cross section of a typical conductor and insulation arrangement for core and shell form transformers. Upon occurrence of a short circuit, a certain amount of heat is rapidly imparted into copper, raising its temperature. During the heating period and during the first part of the cooling period the heat from the copper diffuses into the insulation, the rate of this depending upon time, thermal diffusivity, and the thickness of the insulation. Intuitively, one may expect that on extremely rapid temperature rises all heat will be stored in copper alone, the insulation temperature remaining unchanged. In the next moment insulation immediately adjacent to the copper assumes the same temperature as the copper, the temperature of the remaining part of the insulation being unchanged. Then gradually, as the heat diffuses into the insulation, its temperature increases, while that of copper decreases. Simultaneously, the process of heat loss by convection to oil begins.

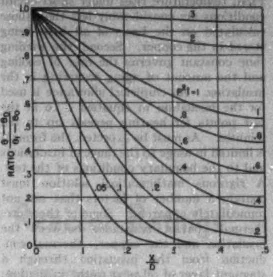

Figure 4. Transient temperature rise in insulation between conductors

When the duration of the short circuit is finite, it appears that the two processes, that of heat generation in the copper, and the heat diffusion into insulation, are simultaneously present, the result of which will be that the copper will never attain the temperature corresponding to all heat stored in copper. However, if the thermal transient in the insulation is of long duration compared to the duration of the short circuit, the insulation will progressively play a decreasingly smaller part as the duration of the short circuit decreases. Hence, in the calculation of the copper temperature the effect of the thermal capacity of insulation must be related to the duration of the short circuit.

The required quantitative relation may be obtained by considering heat diffusion from two parallel surfaces, S and S_1, whose temperature was suddenly changed from θ_0 to θ_1, into a slab of insulation, included between them of thickness D, whose initial temperature is θ_0, Figure 3(C) of the discussion. It can be readily appreciated that this corresponds closely to the insulation included between turns, or between layers in cylindrical windings. Under this condition the transient temperature within the slab is given by a differential equation

$$\frac{\partial\theta}{\partial t}=\alpha\frac{\partial^2\theta}{\partial x^2} \qquad (1)$$

where

θ = temperature at time t minutes and at point distant x inches from surface S

$\alpha=\frac{K}{\rho c}$, is the thermal diffusivity of the insulating material, square inches, divided by minutes

K = thermal conductivity of insulation, $\frac{\text{watts}}{\text{inch}\times\text{degrees centigrade}}$

ρ = density of insulation, pounds per cubic inch

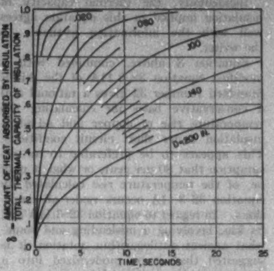

Figure 5. Heat absorbed by conductor insulation under transient conditions

c = thermal capacity, $\frac{\text{watt minutes}}{\text{pounds, degrees centigrade}}$

Solution of equation 1, satisfying the necessary boundary conditions, is

$$\theta=\theta_1-(\theta_1-\theta_0)\frac{4}{\pi}[\epsilon^{-p^2t}\cdot\sin qx+$$
$$\epsilon^{-(3p)^2t}\cdot\sin 3qx+\epsilon^{-(5p)^2t}\cdot\sin 5qx+\ldots \qquad (2)$$

Where

$$p=\frac{\pi\sqrt{\alpha}}{D}, \quad q=\frac{\pi}{D}$$

Equation 2 is presented graphically, on Figure 4 of the discussion, as a family of curves.

Under the transient temperature distribution the effective thermal capacity of insulation is reduced by a factor δ, whose value is equal to the ratio of the mean and the maximum temperatures obtained from any one of the curves, Figure 4. Figure 5 of the discussion gives values of factor δ, as defined above, calculated for the following values of thermal conductivity, capacity, and density which apply reasonably well to oil-soaked manila paper insulation

$$K=0.0042\ \frac{\text{watts}}{\text{inches, degrees centigrade}}$$

$$\rho=0.035\ \frac{\text{pounds}}{\text{cubic inches}}$$

$$c=18\ \frac{\text{watt minutes}}{\text{pounds, degrees centigrade}}$$

As can be seen from the curves of Figure 5 of the discussion, the heat penetration into insulation is quite rapid for relatively thin insulation. Thus for a heating period of five seconds, and for insulation thickness less than 0.050 inch, the insulation is more than 90 per cent effective in absorbing the heat from the copper. This is not so for heavier insulation, for which the time lag in absorbing the heat from the copper may be quite considerable. Curves of Figure 5 may be used in the calculation of the copper temperature rise, if factor δ from Figure 5 is introduced into equation 4 of the paper

$$c=3+2\delta\frac{A_i}{A_c} \qquad (3)$$

Incidentally, the thermal capacity of insulation implied in this equation agrees well with the information available to the writer.

Equation 3 above, combined with a modified equation 32–3.11A of the AIEE Standard Number 32 gives a rational and a conservative basis for calculating the temperature rise of copper and adjacent insulation under short circuit conditions. This appears to be preferable to an assumption that 80 per cent, or what it may be, of the temperature rise calculated by equation 32–3.11A occurs under all conditions. In regard to equation 32–3.11A and its kin, involving a misleading and somewhat ancient antilogarithm notation, it is suggested that it be modernized into a directly usable exponential form

$$\theta = T_0\left[10^{\frac{W_0 t}{mCT_0}} - 1\right]$$

or

$$\theta = T_0\left[\epsilon^{\frac{W_0 t}{CT_0}} - 1\right] \tag{4}$$

for equation 32–3.11A, and

$$\theta = T_0[\epsilon^{At} - 1] \tag{5}$$

with

$$A = (1.38)10^{-10}\,\frac{D^2E}{C} \tag{6}$$

for equation 9 in the paper. In the above ϵ is the base of natural logarithms.

V. M. Montsinger and **G. H. Halsey:** The paper was intended to present two important facts for further consideration. First, temperature rises under short-circuit conditions are considerably less than those calculated on the basis of all heat being stored in the copper. Second, the winding time constant governs the rate of cooling and the amount of aging occurring in the insulation. An empirical allowance is used for the insulation in equation 4 to fit the test points for heating periods up to ten minutes. As must be expected, the formula is limited in usage to the range of insulations and to the boundary conditions of the test. A rigorous mathematical solution must contain a number of factors that are not immediately apparent. Some of these are: thermal contact resistance between the insulation and the copper; thermal conduction from the insulation through a stagnant layer of oil next to the insulation; and heat transfer rates across these two boundaries that are functions of temperature.

A solution embodying some of these features has been made and was thought to be too involved to be easily used. The solution presented by Mr. Narbutovskih may be found in various textbooks[1] for the assumed boundary condition that the inner face of the insulation in contact with the copper reaches ultimate temperature at time $t=0$. As a result of this assumption, one calculates a more rapid heat flow into the insulation than actually exists. The insulation temperature will not rise as fast as indicated in Figures 4 and 5 of his discussion. Effects of the process of heat transfer through the stagnant oil layer and subsequent convective heat transfer to the main body of oil are included in the empirical formula of the paper.

The paper suggests that since most windings with normal turn insulation reach only 80 per cent of the temperature rise calculated on the basis of all heat stored that this figure be used in setting a new temperature limit of 220 degrees centigrade instead of 250 degrees centigrade and that future calculations be made on a more rational basis.

We note that Mr. Narbutovskih has suggested the use of the exponential form of equation 32–3.11A of AIEE Standard Number 32, and we recommend the use of amperes per square inch instead of watts per pound for the convenience of the designer and to be sure that eddy losses are included properly. When watts per pound is used, the figures must be corrected for the decrease of eddy loss with temperature. The principal objection one may have to the empirical factor for eddy loss as expressed by E in equation 9 is that the formula is approximate and not mathematically correct. Reference to Table VIII will show that the results obtained are accurate enough for all practical purposes.

We wish to thank Mr. Narbutovskih for pointing out an error in Figure 2 of the paper. The 550-ampere curves should have been labeled for 600 amperes. References made to 550-ampere tests in Tables II and III should be changed to 600 amperes. The exponent in equation 1 should be changed to $-1/(n-1)$. In Figures 3 and 4, the letter B should be changed to τ and the watts per pound value of 155 in Figure 3 should be changed to 255.

The loss-of-life paper suggested by Mr. Mason should prove helpful in future computations.

Standardization of Reactor Ratings

F. H. KIERSTEAD
MEMBER AIEE

J. L. THOMASON
MEMBER AIEE

REACTORS are used widely for numerous applications in power and other equipment and they are accepted apparatus for limiting fault currents in power systems. Repetitive manufacturing offers economies which can best be realized in reactors when definite physical sizes are frequently duplicated. Before the physical sizes can be duplicated, it is necessary to standardize the ratings of reactors. There are several items of ratings which normally appear on the nameplates, and some of the most pertinent items such as voltage, current, and inductances will be discussed further. While it is advisable to standardize the ratings of all types of reactors that are made in quantity, for illustrative purposes only current-limiting reactors will be considered here. The advantages obtained from the standardization of other types of electric equipment are largely applicable to reactors.

Voltage Classes

The voltage rating of a current-limiting reactor establishes two features: the insulation strength for voltage stress; and the mechanical strength for short-circuit stress.

The latest issue of the Report of the Joint Committee of the Edison Electric Institute and the National Electrical Manufacturers Association "Preferred Voltage Ratings for A-C Systems and Equipment"[1] establishes the nominal system voltages and their range at substations and on transmission systems. These, then, are the voltages to which reactors are subjected in the general application. Hence, these voltages should establish the voltage ratings of current-limiting reactors as listed in Table I.

Current Classes

The continuous current ratings of current-limiting reactors have been established by past usage. Table II shows the present standards for circuit breakers, current transformers and reactors, and also, the recommended reactor current ratings. Included are current ratings that would be established by the preferred series of numbers, 60 per cent and 25 per cent steps; and it is recommended that the use of the 60 per cent steps be emphasized to reduce the number of standard sizes. It is recommended that current classes other than those tabulated be considered specials. However, it is recommended that the specials be placed in preferred sizes as 12 per cent and 6 per cent steps. The short-time current rating of current-limiting reactors is well established by ASA C57.16–1948[2] by the maximum allowable temperatures of 350 degrees centigrade, class *B*, or 250 degrees centigrade, class *A*, for maximum current for five seconds. For neutral grounding devices AIEE Standard 32[3] gives rated time and temperatures rise for short-time ratings. The rating of current-limiting reactors could be matched with the continuous and 5-second rating of circuit breakers for the minimum cost of this natural combination. Further study will be made on this.

Inductance Unit—The Ohm

The reactor is fundamentally an inductance coil and the fundamental unit of inductance is the henry. However, system engineers like an easier applied unit such as the ohm or per cent IX. For standardization purposes, fractions of the henry would be best as the rating in ohms is directly proportional to the frequency. If the reactor is rated in per cent IX it will have an added variable of circuit volts which may vary from the standard classes. Since a large percentage, possibly 95 per cent, of the current-limiting reactor applications are at 60 cycles, it is recommended that current-limiting reactors be rated in ohms at 60 cycles.

The relation between per cent IX and ohms at 60 cycles is given in Figure 1 which shows the relation

$$\text{Ohms} = \frac{\text{per cent } IX}{100} \times \frac{\text{circuit volts}}{\text{amperes } \sqrt{3}}$$

In Figure 1 the reactor amperes as ordinates and the ohms as abscissas are plotted on log-log paper. Two other variables are needed if the reactor is to be rated as per cent IX; these are shown as circuit volts and per cent IX. Four examples are given on Figure 1. Example 1 calls for 0.100 ohms and 300 amperes and the heavy lines indicate their intersection

F. H. KIERSTEAD and J. L. THOMASON are with the General Electric Company, Pittsfield, Mass.

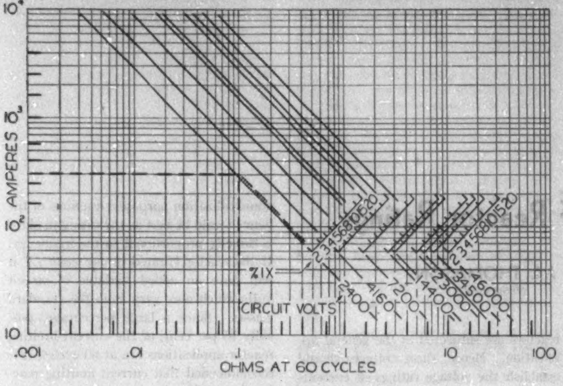

Figure 1. Reactor ratings, ohms and amperes by preferred sizes

$$\text{ohms} = \frac{\text{Per cent IX}}{100} \times \frac{\text{circuit volts}}{\text{amperes } \sqrt{3}}$$

Examples:

	Ohms	Amperes	Circuit Volts	Per cent IX
1.	0.100	300	2,400	2.2
2.	10.00	400	46,000	15.1
3.	0.250	2,000	14,400	6.0
4.	0.100	1,200	7,200	2.9

point. To obtain the per cent *IX* at 2,400 volts project this ohm-ampere intersection point parallel to the voltage line until it intersects the per cent *IX* line—in this case 2.2 per cent *IX*. Other circuit volts and per cent *IX*'s can be secured by interpolation. The kilovolt-ampere per phase is equal to $I^2X/1{,}000$; lines could be placed on Figure 1 to show this relation, but a small graph would become crowded. Figure 1 shows how logically the preferred series of numbers establishes both ohms and amperes.

Inductance Sizes—Preferred Steps in Ohms

It is recommended that the inductance values of current-limiting reactors be expressed in terms of ohms at 60 cycles by sizes according to the preferred series of numbers, ASA-Z-17, 1-1936.[4] Table III shows a range of values which amply cover most applications. The use of the 60 per cent steps should be encouraged. Experienced system engineers would probably find that ratings in the 60 per cent and 25 per cent steps could generally be used and that other ratings could be considered as special cases. However, the special cases should be handled in a logical manner as by 12 per cent and 6 per cent preferred sizes. It might be helpful to note that in the preferred series of numbers, 60 per cent steps means that between two consecutive steps there is a difference of 60 per cent, for example, 100 amperes and 160 amperes. Furthermore, the 60 per cent steps correspond to the five series (that is, 5 steps between decimal units such as 10 and 100), 25 per cent to the 10 series, 12 per cent to the 20, and 6 per cent to the 40.

* 60 per cent steps (or five series), all are 25 per cent steps (or ten series).

Rating Target

To show the ease with which current-limiting reactors with standard ratings could be applied and ordered, a typical rating target is shown in Table IV. The standard ratings in ohms and amperes are given. The minimum enclosure space required and other data could be tabulated. A separate sheet may be required for each circuit voltage class. This rating target shows that in comparison with an infinite number of special rated (or tailored-made) reactors that with preferred sizes the number of ratings become reasonable in the practical range of per cent *IX* of 3 to 10. On Table IV the X's indicate six ratings of ohms for each current, and for the nine ratings of current a total of 54 standard sizes of reactors for this voltage class. For the 10 voltage classes recommended in Table I for air insulated reactors, there would be 540 standard sizes of reactors. However, the lower and higher ratings are infrequently used, and thus, the number of frequently used standard sizes would probably reduce to 5 by 5 by 5 = 125.

Specifications for Current-Limiting Reactors

Current-limiting reactors should meet the following specifications:

1. Withstand the dielectric test in the rated insulation voltage class.
2. Withstand the short-circuit force in the rated circuit voltage class.
3. Not exceed allowable temperature rise for continuous and short-circuit ratings.
4. Meet the tolerance for variations in in-

ductance as established by ASA C 57.16–1948[2] as minus 3 per cent plus 7 per cent, or in effect ±5 per cent. When the standardization is developed so that frequent duplications are manufactured, the actual variations will probably be less.

Standard Physical Sizes of Reactors and Enclosures

After the ratings of reactors have been standardized, the physical sizes should be standardized. Experience should establish the most practical designs to keep at a minimum material, floor space, heating, and so forth for the lowest cost. The definite trend toward the use of enclosures would allow a recommended practice to be set up between enclosure and reactor sizes.

It may be desirable to standardize the reactor enclosure sizes with the sizes of other metal-clad equipment. However, three items should be pointed out. First, in the past, metal-clad enclosure sizes have fluctuated from time to time. Second, if metal-clad enclosures are going to be standardized, the sizes should be established by definite steps (as six inches) in depth, width, and height, or the sizes should be established by the series of preferred numbers. Third, it must not be overlooked that reactors dissipate heat and that clearances must be provided for air circulation.

Enclosure sizes could be established by minimum height and inside dimension for maximum reactor voltage and kilovolt-amperes as suggested in Table V. Adequate strike distance and working space inside should be provided. Special sizes will probably be required occasionally.

Advantages of Reactor Standardization

Some of the advantages of reactor standardization are:

1. Acceptance of preferred ratings should eventually result in: reduced costs; shorter delivery time; better use of materials as tests and service on the same size of reactor will point to improvements.

2. Standardizing on ohms on a 60-cycle basis rather than on per cent *IX* will be very helpful in promoting preferred ratings.

3. The use of preferred sizes (as on a rating target) will allow reactors and enclosures to be designed and used in logical sizes. Enclosure sizes and designs can then be made to harmonize with other metal-clad equipment.

4. Voltage and current ratings will be in agreement with accepted standards.

Discussion

J. A. Elzi (The Commonwealth and Southern Corporation, Jackson, Mich.): There is no question as to the desirability of standardization of certain types of reactors which are used on power systems; particularly those used on distribution circuits to protect feeder voltage regulators, distribution equipment in underground vaults, and those used to limit fault currents and thus reduce shock to the system and circuit breaker duty. However, some of the recommended standard values given in this paper should be given further consideration.

Voltage Classes

It seems that since the EEI-NEMA preferred voltage report[1] stops at 230,000 volts, it is undesirable to include the higher voltages which still have not been standardized. In fact, for the type of standardization discussed in this paper, that is, reactors that are used in quantity, it appears that the standardization should terminate with the 23,000- or 34,500-volt rating.

Current Classes

The authors mention that continuous current ratings of current limiting reactors have been established by past usage and in Table II a comparison is made between present American Standard Association preferred reactor current ratings and the current ratings of circuit breakers and current transformers. It is not felt that the comparison is parallel. The latest ASA circuit breaker tables[2] start with a continuous current rating of 600 amperes and a large number of standard reactor ratings would be below this value. In the case of the current transformers, the current ratings are influenced by the requirements of instruments and relays and do not necessarily indicate the requirements for reactors. The applications where reactors would be used in numbers would be on distribution circuits and the current ratings chosen should be such as to meet the requirements of such circuits. It would seem very important to co-ordinate the reactor current ratings with the preferred current ratings of feeder voltage regulators. There is some evidence that the current ratings of regulators need revision, but it is felt that the current ratings of the regulators and reactors should be co-ordinated.

The authors recommend the use of ratings based on a preferred series of numbers. This is probably a good method of arriving at the steps in general, but from practical considerations it is thought that for purposes of standardization it would be advantageous to avoid such numbers as 160 amperes, 315 amperes, and so forth. For practical purposes these could just as well be 150 amperes, 300 amperes, and so forth.

Inductance Unit

The authors' recommendation that the ohm be used as the standard unit to express inductance would, it seems, be detrimental rather than helpful in promoting preferred ratings. Application engineers are interested in the percentage drop introduced by reactors and in most cases would have to convert ohms into per cent in making their calculations. The per unit or per cent method is widely used for circuits and other apparatus, and we feel that the use of ohms for standard reactors would be very unsatisfactory. It is true that for certain types of reactors the use of ohms is desirable, but these would fall into a minor class and need not affect general standardization.

Standard Physical Sizes

The authors have an excellent point in recommending standardizing of physical size. It appears that this should be entirely practicable and would certainly be welcomed by the users.

2. PREFERRED RATINGS FOR POWER CIRCUIT BREAKERS, *C37-6-1949*. American Standards Association (New York, N. Y.), 1949.

N. E. Dillow (General Electric Company, Schenectady, N. Y.): The authors have shown that there are many advantages to be gained from reactor standardization. However, when the question of standardization is raised in any line of apparatus the question arises as to the limitations in the application of the standardized line. It therefore appears desirable to consider the proposals made by the authors from the application viewpoint.

The nominal voltage ratings for reactors listed in Table I of the paper are chosen from the listings in the EEI-NEMA report. Considering system application, current-limiting reactors will generally be installed where they are subjected to voltages tabulated in the EEI-NEMA report as the range of the tolerable zone for voltages at substations and on transmission systems. The values listed in Table I of the paper as the maximum design voltage rating agree with the maximum of the tolerable zone. Hence, the proposal should adequately meet the application requirements as to voltage ratings.

Current-limiting reactors generally are applied in series with circuit breakers and current transformers. It is for this reason, probably, that the authors have listed the present American Standard Association current ratings for these equipments in addition to the recommended reactor ampere ratings. There is reasonable correspondence among the columns, and from an application viewpoint, the ampere ratings listed in Table II of the paper as the preferred sizes (60 per cent steps) appear to offer sufficient choice of current ratings.

By habit, application engineers have considered the inductive size of a reactor as a per cent reactance. This follows easily from the calculations usually employed to determine the reactance to limit the short-circuit currents or to balance loadings on parallel circuits. However, the conversion of per cent quantities to basic ohmic values also is a step familiar to the application engineer as he must use such conversions in calculations involving wires and cables. Hence, such a proposal to rate reactors in ohms should be acceptable.

Consider an example for the application of the standardized ratings proposed in the paper: assume a 13.2 kv feeder, rated at 5,000-kva capacity. It is desired to limit the 3-phase short-circuit current in the feeder to 100,000 kva maximum. A short circuit on the bus is 250,000 kva. Specify the standardized reactor ratings.

Calculations:

$$\text{Equivalent bus reactance} = \frac{5,000}{250,000} = 2.0 \text{ per cent}$$

(5,000 kva base)

$$\text{Desired feeder reactance} = \frac{5,000}{100,000} = 5 \text{ per cent}$$

Reactor reactance required = 3 per cent
Base ohms (5,000 kva, 13.2 kv) = 34.85 ohms
Reactor ohms = 1.05
Reactor current = 219 amperes

Specify reactor as follows:

Nominal voltage rating = 14.4 kv (Table I)
Continuous current rating = 250 amperes (Table II;
Reactor reactance = 1.00 ohms (Table III)

These ratings are compatible with the application. The reactance specified is actually nearer the calculated value than the accuracy of the usual data justifies. In addition, manufacturing tolerances allowed would permit almost as large a variation as exists between the specified and calculated value.

The proposals of the paper would not place any limitation on the general application of current-limiting reactors.

F. H. Kierstead and **J. L. Thomason:** In also advocating the standardization of reactor ratings but with some controversial suggestions, J. A. Elzi has undoubtedly brought up points which other engineers and members of the AIEE, NEMA, and EEI may wish to consider. The standardization of reactor ratings will be satisfactory to all concerned only if first, there are enough ratings to cover the fields of applications and if second, there are few enough ratings so that economies may be realized.

Regarding circuit voltages, the discusser recommends a top limit of 23,000 or 34,500. Some such limit within a frequently used range would certainly form a practical starting point in the standardization program.

Regarding the current ratings of reactors, the problem again seems to be basically economics:

First, it would appear that if all apparatus carrying the same current had the same current rating, the cost of the whole group would be a minimum. Second, it is undoubtedly more economical to supply certain apparatus with a higher current rating than needed if this rating is a frequently used standard. Third, the use of current ratings based upon the 60 per cent steps by the series of preferred numbers gives a logical and wide choice of ampere ratings. In the future, as standards are changed, it is recommended that all apparatus be given ampere ratings according to the preferred series of numbers; subdivisions then would be logical and orderly. During or before this transition period it will probably be necessary to retain ampere ratings in the well-established "round number" classes; economies will result when sizes are frequently duplicated.

Regarding the inductance unit, the ohm is considered best for the reasons set forth in the paper. All applications can be calculated on a percentage basis. Then the reactor can be ordered on a standard ohm rating.

The standardization of the physical features of reactors is desirable but is largely dependent upon first achieving standardization of the ratings of the reactors.

Mr. Dillow has analyzed the standardization of reactor ratings from the application viewpoint. He has shown that there are several advantages and no limitation by such standardization.

Use of Thyrite in Power Transformers

J. R. MEADOR
MEMBER AIEE

ELECTROSTATIC shielding long has been recognized as an effective means of controlling the impulse-voltage distribution in transformer windings. Under certain conditions, the same, or a better, result can be achieved by the use of Thyrite.*

The development of Thyrite[1] was reported in 1930. This ceramic-bonded inorganic material, strong, stable, and possessing precise electrical characteristics, is characterized by its nonlinear resistance; it passes a current proportional to a relatively high exponent of the applied voltage. Developed as a material for lightning arresters, its versatility is attested by its many important applications. One of these is the part it takes in the internal protection and "shielding" of power-transformer windings.

The increase in complexity of power transformers, particularly from a circuit standpoint, has been so gradual as to be almost imperceptible. A comparison between the modern transformer and its 25-year-old counterpart, however, reveals startling differences. The simple 2-winding machine with a ten per cent tap range, typical of the vast majority of transformers formerly produced, now represents an ever-diminishing share of power-transformer production. On the other hand, the enormous increase in the use of autotransformers, regulating transformers, load-ratio-control transformers, and transformers with complicated winding arrangements and wide tap ranges has introduced to the designer new problems of winding protection against overvoltages. Thyrite, immersed in the transformer oil and shunting portions of the windings, has, in the past ten years, achieved a prominent position in the solution of these problems.

Although the use of Thyrite in transformers, as described in this paper, has proved eminently successful for effectively controlling overvoltages within the transformer, this advance does not eliminate the necessity for normal protection consisting of modern lightning arresters connected from line to ground in the station, and overhead ground wire shielding of the station structure and at least 2,500 feet of connected transmission lines adjacent to the station.

Thyrite Characteristics

Thyrite used in transformers is normally in the form of standardized disks, either $1^1/_2$ inches thick and 3 inches in diameter, or 3/4 inch thick and 6 inches in diameter (Figure 1). Its high mechanical strength, about 23,000 pounds per square inch in compression, and its electrical and thermal stability under pressure or vibration make for trouble-free performance.

The volt-ampere characteristic of transformer Thyrite is

$$I = KE^N$$

where I and E are the instantaneous values of current passed and voltage applied, respectively, and K and N are constants depending on the disk dimensions and constituents. The constant K can be controlled over a wide range of values.

The exponent N is usually of the order of 3.5, so that an elevenfold current increase through the Thyrite causes only a doubling of the voltage across it. Since the volt-ampere relationship is independent of time, it applies equally to alternating, direct, or impulse voltages and currents, as long as instantaneous values are considered.

While Thyrite can be used continuously at 110 degrees centigrade, and for short periods at 150 degrees centigrade, the limit maintained in transformers is the same as the winding hot spot temperature; that is, 95 degrees centigrade.

Application in Transformers

Thyrite is used within transformers to perform one or more of three important functions:

1. To limit the impulse voltage across the portion of the winding to which it is applied
2. To control the impulse-voltage distribution in the portion of winding across which it is connected.
3. To establish and fix the potential of momentarily or continuously "floating" windings. This application is not discussed in this paper.

In the first case, a portion of winding is shunted by a stack of Thyrite disks and the nonlinear character of the material is such that at normal power-frequency operating voltages, its resistance is sufficiently high so as to have no measurable effect on the transformer. When carrying high surge currents, however, its resistance falls and limits the voltage drop across it and across the connected portion of the winding to a predetermined safe level.

In some instances, additional protection is needed, and the Thyrite is called upon to serve its second function. It is a well-known fact that a transformer winding is a rather intricate network of inductances interturn and intercoil capacitances, and capacitances to ground. At normal operating frequencies, the capacitances can be disregarded and the winding considered as a nearly pure inductance with a uniform linear distribution of voltage throughout its length. Under impulse conditions, the capacitances become prominent and alter the voltage distribution. Thus, intermediate parts of the Thyrite-shunted winding may develop high voltage gradients even though the voltage between the ends of the

Paper 49-192, recommended by the AIEE Transformers Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer General Meeting, Swampscott, Mass., June 20–24, 1949. Manuscript submitted February 10, 1949; made available for printing May 2, 1949.

J. R. MEADOR is with the General Electric Company, Pittsfield, Mass.

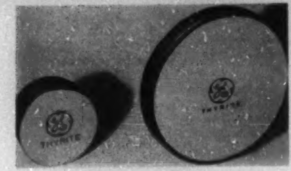

Figure 1. Thyrite disks: 3 inches in diameter and 1 1/2 inches thick; and 6 inches in diameter and 3/4 inch thick

winding is controlled by the Thyrite. If, now, intermediate points of the winding are connected to intermediate points of the Thyrite stack, the voltage distribution in the winding can be made to approach its normal power-frequency linearity. This follows from the fact that the Thyrite stack behaves as a pure resistance which is quite low under high transient voltages compared with the impedance of the shunted winding, and consequently it divides the voltage uniformly along the Thyrite and winding.

Before going on to a detailed examination of some of the applications, it is well to distinguish briefly between the employment of Thyrite in transformers and in lightning arresters. Gaps are not used in series with the Thyrite disks in the transformer; hence, the resistance of the Thyrite must be high enough at normal power-frequency operating voltage to limit the heat loss to a value easily dissipated into the oil. In valve-type lightning arresters, which utilize gaps to seal the power-frequency follow current after discharge of an impulse through the arrester, a lower Thyrite resistance at normal operating power voltage is permissible, since the Thyrite valve element is disconnected from the circuit except during, and immediately following, an impulse discharge.

Thyrite Across Taps in Transformers

Almost all transformers have taps in one or more windings for changing the turn ratio. In a simple 2-winding transformer with, say, four $2^1/_2$ per cent taps, the taps introduce no particular problem to the designer, since the only winding structures that are used are those that can be tapped. A line of standardized ratio adjusters is normally available to cover the usual range. The problem of the number and type of ratio adjusters to provide is a simple question of economics. It is obviously impractical to design a new ratio adjuster for every transformer. It is equally impractical to expect one or two ratio-adjuster designs to fill economically the needs of all transformers.

Ratio adjusters basically must meet two requirements:

1. The insulation between adjacent taps and across the tap range must withstand the continuous voltage to which it is to be subjected.
2. The insulation between adjacent taps and across the tap range must withstand the impulse voltage that appears in the portion of the winding to which it is connected.

Thus, a ratio adjuster normally has a double rating; (a) the voltage at which it can be continuously operated; (b) and a safe withstand impulse strength between its parts.

The method of application of the first rating is obvious. Its selection from the standpoint of the second rating depends on the insulation level of the winding, the percentage of the winding connected across the ratio adjuster, and the impulse-voltage distribution in the winding. Unless these conditions are known and met, there can be no assurance that the adjuster application is correct.

In very-high-voltage transformers or for abnormally large tap ranges, there is often a choice between using a high-voltage ratio adjuster in the normal way or using a lower-voltage ratio adjuster and shunting all or part of the tap range with Thyrite.

The choice is made on the basis of over-all economy. If a certain adjuster meets rating but is inadequate on rating, it is sometimes to advantage to shunt all or part of the taps with Thyrite and thereby bring the tap-range impulse requirements down to the rating of the adjuster.

Sometimes, because of some unusual design requirement, the impulse-voltage distribution in the tap winding may be difficult to calculate with a sufficient degree of accuracy. In such cases, the predictability of the Thyrite-shunted taps may justify the use of Thyrite.

The two usual types of tap connections and the shunting Thyrite are shown in Figure 2(A) and 2(B).

A typical example of the quantitative effect of the Thyrite shunt across the tap range is shown by the test points plotted in Figure 3. The 10.5 per cent tap range is shunted with Thyrite. By changing the number of disks, the impulse voltage across the taps can be held to almost any desired level as shown by the curve. In general, the Thyrite is selected to permit the tap range to have its normal share of the applied impulse voltage (that is a 10 per cent voltage for a 10 per cent tap range).

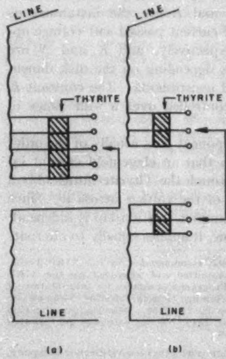
Autotransformers

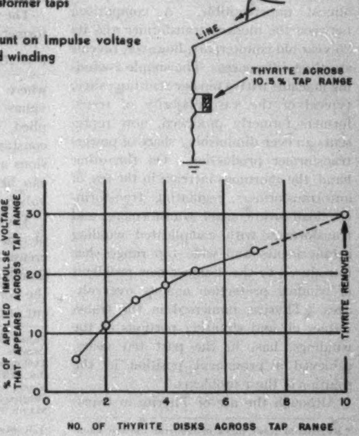
Thyrite is particularly useful in autotransformers. To explain these applications, it is necessary to mention briefly some of the rather exacting demands of autotransformer designs. From an insulation standpoint they are as follows (refer to Figure 4):

1. High-voltage (*HV*) taps may be for ten per cent of the terminal voltage, but if the co-ratio is low (such as in a 138-kv grounded wye to 115-kv grounded wye), the taps may be 30 to 50 per cent of the series winding.

Figure 2 (below). Thyrite across transformer taps

Figure 3 (right). Effect of Thyrite shunt on impulse voltage across taps in unshielded winding





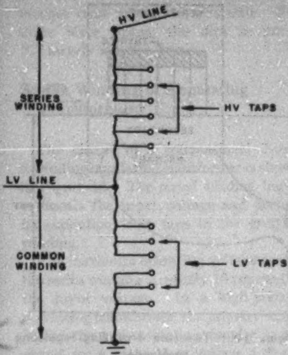


Figure 4. Autotransformer with taps in common and series windings

2. Although only a small percentage of the turns from the high-voltage terminal to ground may be in the series winding, a large percentage of the voltage appears across the series winding when an impulse voltage is applied to the high-voltage terminal. This is caused by the relatively low impedance from the low-voltage (*LV*) terminal to ground which results from connecting the low-voltage terminal to a transmission line or other similar load.

3. It is often desirable to place taps in the common winding immediately adjacent to the low-voltage terminal, rather than in the middle of the common winding as was shown in Figure 4.

4. The series winding may have an impulse voltage applied to either of its terminals. While this condition is the same as that in any delta-connected winding, nevertheless it introduces special problems when it occurs in combination with some or all of the aforementioned requirements.

The role of Thyrite in helping to meet these demands will be discussed in detail.

An example of items 1 and 2 is shown in Figure 5. An autotransformer rated 132-kv grounded wye to 62.7-kv grounded wye has taps for changing the voltage from 115.5 kv to 141.9 kv. While this range is 20 per cent of rated voltage, the taps are 33 per cent of the series winding. Impulse-voltage distribution tests were made for two different conditions: with the low-voltage terminal grounded; and with 630 ohms connected from the low-voltage terminal to ground. In both cases, the ratio adjuster was set on the minimum tap, and the impulse was applied to the high-voltage terminal. Under these conditions, the impulse voltages measured were as follows:

Resistance, Ohms, Low-Voltage Terminal to Ground	Per Cent of Applied Voltage Across Series Winding	Per Cent of Applied Voltage across Ratio Adjuster and Tap "Break"	
		With Thyrite	No Thyrite
630	80	31	51
0	100	29	63

The two conditions of "loading" the low-voltage terminal represent a wide range of service conditions. The Thyrite shunt across the taps holds the tap-range voltage to a relatively constant, normal magnitude. It should be added that the series winding in this case was well shielded electrostatically. The improvement brought about by the Thyrite would have been much greater in an unshielded winding since the tap voltage without Thyrite would have been much greater.

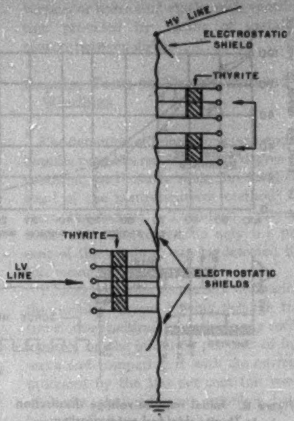

Figure 6. Autotransformer having common-winding taps located at the low-voltage line

Figure 4 shows taps located in the center of the common winding. Placing these taps immediately adjacent to the low-voltage line is a safe procedure if the taps are shunted with Thyrite as shown in Figure 6. Without a Thyrite shunt, this is a hazardous practice because of the high transient voltages that may exist across the tap coils, tap leads, ratio adjusters, and so on.

Furthermore, if the low-voltage line voltage is such that electrostatic shields are used, the Thyrite shunt permits the shields to be fully effective when connected at the extremities of the tap range as shown in Figure 6. When an impulse voltage is applied to the low-voltage terminal, the charging current to the shields is furnished through the Thyrite instead of through the series capacitance of the tap portion of the winding.

An extreme example of autotransformer taps is shown in Figure 7. In this case, two systems of essentially the same voltage were connected by this auto-

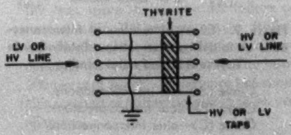

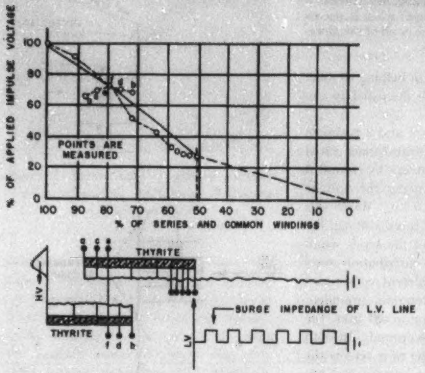

Figure 8. Initial impulse-voltage distribution in Thyrite-shielded series winding

transformer with the expectation that power might flow in either direction. The problem here is similar to that illustrated by Figure 6. With a Thyrite shunt, taps can be placed at any location in a winding without fear of transient-voltage trouble.

Item 4 in the autotransformer design requirements concerns the impulse-voltage distribution in the untapped portion of the series winding. As has been shown, the major portion of the impulse voltage reaching the high-voltage terminal may appear across the series winding. Consequently, in medium- and high-voltage transformers, the series winding usually must be shielded.

In general, an electrostatic shield is used to nullify the ground capacitance of a winding so as to achieve a reasonably uniform impulse-voltage distribution in the winding. In this way, harmful concentrations of voltage are avoided. Shields are very effective and their application is straightforward in transformers of normal proportions.

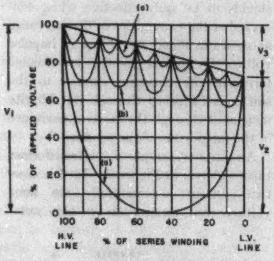

Figure 9. Effect of number of interconnections on initial impulse-voltage distribution in Thyrite-shielded series winding

Curve (A)—no interconnections
Curve (B)—four interconnections
Curve (C)—nine interconnections

Occasionally, the untapped portion of a series winding is so small physically or contains such a small number of turns that conventional electrostatic shielding is inadequate to maintain a reasonable impulse-voltage distribution. This condition is aggravated by an abnormally large tap range. Optimum shielding designed for one tap connection may leave much to be desired for a widely different tap connection.

Figure 8 shows how Thyrite has been used to advantage for such a condition. The conventional shields are omitted from the series winding, and the entire winding (including the taps at the low-voltage terminal) is shunted by Thyrite. By connecting the Thyrite and the winding together at numerous points, essentially straight-line initial voltage distribution is obtained throughout the winding in the circuit for all tap connections. In this case, with a surge impedance from low-voltage terminal to ground corresponding approximately to the surge impedance of the low-voltage line, some 70 per cent of the applied voltage appears across the series winding, although the turns in the series and common windings are about the same. It will be noted that the "overhanging taps" (with tap *e* connected to tap *f*) in the series winding that are not in the circuit all are held at essentially the same potential.

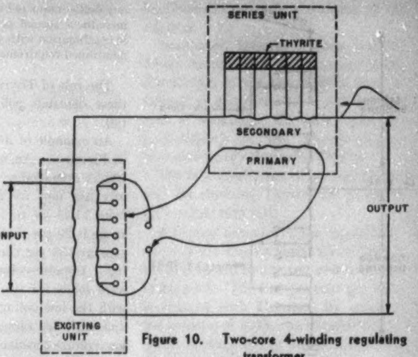

Figure 10. Two-core 4-winding regulating transformer

An interesting problem relating to the "shielding" of series windings by Thyrite concerns the necessity for interconnections between the windings and the Thyrite. It may be asked why the same result can not be obtained using an unshielded series winding and a lightning arrester connected across the terminals of the winding. The arrester will definitely limit the surge voltage appearing between the high-voltage and low-voltage terminals. It may, however, have little, if any, effect on the internal voltages (between turns and coils and between taps) in the winding. Figure 9 shows what happens.

Curve (A) of Figure 9 shows the initial impulse-voltage distribution in a series winding when an impulse voltage V_1 is applied to the high-voltage terminal and the impulse voltage across the winding is limited to voltage V_3 by Thyrite or an external lightning arrester connected from the high-voltage to the low-voltage terminal. The effect is similar to that resulting from simultaneously applying voltages V_1 to the high-voltage terminal and V_2 to the low-voltage terminal. The charging currents from winding to ground are not nullified, and the center of the winding may be at essentially zero voltage at the same instant that the terminals of the winding are at their maximum voltages. The actual voltage gradients near the ends of the winding may be very large if no electrostatic shielding is used.

Curve (B) of Figure 9 shows how the initial distribution is changed by providing four intermediate connections between the winding and the Thyrite. Curve (C) of Figure 9 shows a typical initial distribution when a larger number of interconnections are made. There is a very substantial reduction in internal stresses in the winding. These curves are calculated assuming a wave front that reaches crest voltage in zero time. For finite wave fronts, the dips in curve (C) largely will disappear.

Series Winding of Regulating Transformers

The circuit of a conventional 2-core 4-winding regulating transformer is shown in Figure 10. The series winding bucks or boosts the input voltage and derives its excitation from taps in the exciting winding.

The maximum operating voltage across the series winding is usually 10 per cent of the input voltage. In a high-voltage regulating transformer, the primary winding of the series winding usually is designed for a rather low voltage to keep down the size of the tap-changing equipment. In many cases, the primary and secondary windings of the series transformers have approximately the same number of turns.

As has been pointed out for autotransformers, when an impulse voltage is applied to the high-voltage terminal, the majority of the voltage appears across the series winding. The same phenomenon occurs in a regulating transformer. It is well known that electromagnetic transfer of impulse voltages occurs between transformer windings, the induced voltage being in the ratio of the turns in the two windings in many cases.

Referring again to Figure 10, assume that the input voltage is 115 kv wye and the maximum series-winding voltage is 11.5 kv wye (6.64 kv phase voltage). Also, assume that the primary winding of the series transformer is 6.64 kv phase voltage, which is a reasonable voltage for tap-changing purposes. (In other words, the turn ratio of the series transformer is one to one).

When an impulse is applied to the output terminal of a magnitude consistent with the protective equipment on a 115-kv system, the bulk of the voltage may appear across the series winding. This voltage, under some conditions, will be transferred into the low-voltage winding at the turn ratio of one to one. That is, the bulk of the impulse voltage that can appear on a 115-kv system will be transferred into the low-voltage tap-changing circuit of the regulating transformer. The exact amount of the voltage depends mainly on the surge impedance of the input line, the leakage reactance of the transformer, the tap connections being used, and the length of the applied impulse wave.

It is obviously impractical to design the primary circuit for such high voltages. The solution is to limit the voltage across the series winding by shunting the winding with Thyrite or with an external lightning arrester. In high-voltage circuits, this brings up the same problem as that encountered in autotransformers and illustrated by Figure 9. Thyrite across the winding, connected at a proper number of intermediate points, not only limits the voltage appearing across the winding, but also distributes the surge voltage uniformly across the winding. (Under some conditions it is desirable to use Thyrite across the winding for voltage-distribution purposes, and, in addition, to shunt the winding with an external lightning arrester.)

Precautions Observed in Use of Thyrite

Thousands of Thyrite disks a year are used in power transformers in the manner described in this paper. None has failed to function properly in service. This 100 per cent service record is largely due to the care used in the Thyrite applications.

After manufacture, every Thyrite disk is tested for resistivity and stamped with a marking that is keyed to a volt-ampere curve. The transformer designer selects the disks needed from these curves. Before the disk assembly is mounted in the transformer, it is tested for resistivity. The induced voltage test on the completed transformer provides the final test.

Successful application of Thyrite in transformers requires that the same attention be paid to proper supporting and bracing of the Thyrite as is given to the winding and insulation of the transformer.

When a portion of winding is shunted by Thyrite, three thermal requirements are met: the number of disks in series is such that with continuous operating voltage across the Thyrite a temperature of 95 degrees centigrade is not exceeded; the Thyrite loss during induced voltage test (usually 3.46 times normal voltage or less) is within the heat storage capacity of the disks; and the energy input into the Thyrite is within its heat storage capacity during a system fault, when abnormal voltages may appear across a winding (notably, the series winding of an autotransformer).

All of these requirements are subject to calculation and are the basis for the selection of the disks. The insulation between turns, coils, taps, and so on, of the winding is determined from the expected impulse voltage across the Thyrite. Thyrite disks may be mounted in either vertical or horizontal stacks with ventilation provided by means of metallic spacers between disks.

Impulse Tests on Thyrite Shunted Windings

The detection of failures on commercial impulse tests has reached a high degree of precision, particularly since the development of the neutral-current method[3] of wave comparison. Turn-turn failures, where one turn represents only 0.1 per cent of the winding, can be detected by this means.

Failure detection consists of measuring the impulse current flowing through the transformer neutral, by cathode-ray oscillograph, on the initial 50 per cent of full wave and comparing it with the current produced by the 100 per cent full wave after the chopped wave impulses have been applied.

Failure is indicated by a difference in the wave shape. The wave changes because the failure has short-circuited a portion of the winding, and, consequently, the circuit constants of the winding have changed.

When Thyrite shunts part of a winding, the equivalent circuit of the transformer contains a resistor across that part of the circuit. Thyrite, however, does not have a constant resistance. Consequently, the equivalent circuit of the transformer is different for applied impulses of different crest values. Therefore, the neutral-current wave shape changes slightly for different applied voltages; that is, the initial 50 per cent impulse produces a different wave shape from the final 100 per cent impulse.

A new technique has been developed to handle circuits of this kind. Fortunately, as higher impulse voltages are applied to the line terminal, the change in circuit constants produced by the change in Thyrite resistance is gradual and the change in the neutral-current wave shape is gradual. Thus a trend is observable and departures from this trend show failure.

The test technique consists of applying initial full waves of 50, 70, and 100 per cent followed by the chopped waves and ending with a 100 per cent full wave. Comparison of the first two initial waves of 50 and 70 per cent with the initial 100 per cent wave shows whether failure occurred on the 100 per cent wave. Following the chopped waves, the final 100 per cent full wave is compared with the initial 100 per cent wave. Experience has shown this method of failure detection to be very effective.

Conclusions

Thyrite, a nonlinear resistance material, has many effective uses in power transformers. It is another means for controlling transient voltages in windings. It is used to supplement and in some cases to replace electrostatic shielding.

Thyrite has easily determinable and precise electrical characteristics. Its mechanical properties are excellent. As used in transformers, it has very high surge-current capacity, and since no gaps are used, the problem of interrupting follow current does not exist. The low-frequency loss in the Thyrite has little, if any, measurable effect on the transformer characteristics.

Thyrite is particularly useful in autotransformers and regulating transformers where normally certain insulation and transient-voltage problems are more acute than in simple 2-winding power transformers.

The remarkably good service record of Thyrite, which has been used in hundreds of transformers during the past ten years, is a result of careful electrical and mechanical application.

Discussion

W. H. Eason (General Electric Company, Pittsfield, Mass.): Mr. Meador points out that Thyrite possesses "precise electrical characteristics." Because of its nonlinear resistance characteristics, this material has found many other important applications in the central-station, industrial, and electronics fields, notably as discharge resistors for inductive circuits and in voltage stabilizing circuits. Engineers using Thyrite in these applications generally will find that it is necessary to allow electrical tolerances of ±30 per cent in applied voltage at a given current. Mr. Meador's statement and this fact do not at first glance appear to be in agreement and may require further elaboration.

A specific Thyrite disk does possess precise electrical characteristics and is stable over reasonable ranges of temperature and humidity. There are many variables which enter into the complex manufacturing processes involved in producing Thyrite. Each affects the ultimate electrical characteristics to some degree. Elaborate precautions taken during manufacture reduce these variations to a minimum, but their number is such that it is not possible to predict the ultimate electrical characteristics closer than the ±30 per cent indicated. However, dictates of design in circuits utilizing Thyrite generally permit such tolerances.

Every Thyrite disk is tested during manufacture to determine its electrical characteristic. The tolerance may be considerably narrowed by dividing a given "batch" of disks into narrower classes during production testing.

The use of Thyrite in transformers is large enough and the requirements are sufficiently diversified so that various combinations of classes of disks may be selected to give the required characteristics and still utilize the entire production.

The same procedure has been followed in special Thyrite disks made for other high production applications. A case in point is a discharge resistor for protection of large generator fields, which utilizes 20 disks connected in parallel. During manufacture these disks are segregated into three resistance ranges and designated as class *A*, *B*, or *C*. In assembling the resistor, care is taken to use as many class *A* as class *C* disks, so that the over-all electrical characteristics are those of 20 class *B* disks; the tolerance thus is effectively reduced by 67 per cent.

Extremes in the Insulation Co-ordination of Oil Insulated Transformers

F. J. VOGEL
MEMBER AIEE

THE margins obtained and degree of co-ordination between transformers and other insulation in transmission systems depends largely on the possibilities inherent in the insulation design of the transformer. Recently some units have been designed which take full advantage of the impulse characteristics of insulating materials as compared to their 60-cycle strengths. These designs are core form, or at least have concentric coils, and it is likely that they might be considered to have maximum impulse characteristics compatible with present 60-cycle test requirements. It is believed that these characteristics affect, and should be given consideration, in the setting of future required impulse levels and tests, and perhaps in the 60-cycle tests which are required. The basic insulation levels only include full-wave values and it is believed that this is not sufficient for transformers. This matter affects the cost and the service reliability of transformers. It is believed that besides the basic insulation level, either a steep front or other type of test should be included.

Design Considerations and Test Data, 69-Kv Transformers

To illustrate some of the problems confronting both the system and transformer designer, one important design consideration and the results of some tests made in the development of a possible new line of transformers are described.

It is believed that irrespective of present standards, the major insulation, and the turn-to-turn and coil-to-coil insulation should be about equal in impulse strength.

Present rules do not require this relationship, but investigation shows that the saving using a relatively weak winding is small. The designs referred to in this paper were made so that the winding strength is in excess of the insulation strength to ground. Tests to check the design have been made on a 1,000-kva 34.5-kv transformer, a 667-kva 69-kv transformer, and a 69-kv potential transformer. The results of the tests on the 667-kva transformer, which are representative, are shown in Tables I and II. With the exception of the failure to ground on X_1, no failures were found, as X_2 showed no signs of failure. The tests on the 1,000-kva 34.5-kv unit were somewhat similar except that the gap length and voltages were reduced. The 69-kv potential transformer tests were similar to those above. The 667-kv transformers did not fail to ground with a 60-cycle voltage of 160 kv on the high-voltage winding.

ANALYSIS OF RESULTS

Table III shows the actual demonstrated strengths with present American Standards Association (ASA) and National Electrical Manufacturers Association (NEMA) requirements.

Let us analyze these tests. A margin, so that there will be practically no shop failures, is necessary. The extreme right-hand column would not be safe to use as guaranteed values. Margins used differ and are those deemed reasonable by the manufacturer. The margin ensures freedom from injury on test except for defective materials or assembly.

The chopped wave tests under present circumstances do not prove very much, at least, with these designs. If the bushing is flashed over, it indicates that the windings will stand more than the bushing and this characteristic may be desirable. The full-wave test made with the oversize bushing emphasizes the correlation between 60-cycle strength and impulse strength for the core-type construction. If full-wave co-ordination and tests only were required, it is obvious that a large decrease in insulation would be possible, at least in the ratio of 450/410, or nearly one voltage class.

The steep-front tests indicate a larger margin between test and requirements in terms of voltage than actually exists, due to the effect of time and the fact that to meet 580 kv, considerable variation in test conditions requires designing to meet 620 kv or more, with a margin besides.

The question then arises, is the steep front test and NEMA value desirable? In the case of the design of some bushings, flashover would occur, likely porcelain breakage, and possibly even fire. Other bushings have much higher steep front strength. Unless some type of gap is used which will protect both the transformer and bushing, it may not be desirable. But there are two other points of view.

Suppose the user wishes to depend alone on gap protection. It seems likely that a very good degree of protection to the transformer and bushing can be obtained at the expense of some gap flashovers and outages. One user does.

Suppose also that the operator uses line type lightning arresters. Lines of the above ratings are not always well protected. Several cases of bushing flashover and damage even when lightning arresters and ground wire protection were used have occurred. In one case the lightning arrester and transformer were both badly damaged and the operator was extremely irate over what he felt to be a case of poor transformer design. Hence,

Table IV. Steep Front Tests on Model

Number of Tests	Gap Length, Inches	Kilovolts, Average
25	24	800
25	27	850
25	30	1,020
25	33	1,120
25	34½	1,070
50	36	1,100
25	37½	1,100
27	39	1,200
29	40½	1,200

all things equal, it would probably have been better had this transformer been relatively as strong as the one in Table III. In the case of an extremely high rate of current rise, the voltage across a lightning arrester can resemble a steep-front wave, which can be higher at the transformer than at the lightning arrester by as much as 10 to 15 per cent, and will also be longer in time duration. A transformer protected by modern lightning arresters at the terminals, and with strengths in line with Table III would withstand lightning except in extremely rare cases. Further, even in the case of lightning arrester damage or removal, a very considerable margin over most line disturbances would remain, particularly if the gap were added.

If the industry believes that steep front strength is not necessary, the advantages just given may not be obtained. In that case, full advantage of a decrease in insulation within the unit to meet the requirements could not be obtained without decrease in 60-cycle test requirements or destroying the co-ordination within the winding.

To sum up, it would seem desirable, for the 69 kv or lower voltage systems, not to design transformers to depend entirely on the normal published characteristics of lighting arresters, due to the varying degrees of lightning protection on these lines. If this is true, these transformers should have impulse strengths at least in line with present NEMA and ASA rules, both steep front and full wave. It is believed that the use of full waves as a test and standard alone would result in a lower strength of transformers, and there would be some failures, whereas it is understood that practically no lightning failures of transformers designed in the last 15 years now occur.

Design Considerations and Test Data on 138-Kv Transformers

The same design consideration as to major and coil insulation came up with regard to the higher voltage transformers, and it is believed that the windings should be stronger than the insulation to ground. With this in view, tests on some models and on large complete units were made.

Tests on transformer insulation for full and chopped waves have been reported in other papers, and would indicate that 138-kv transformers[1,2] should be able to stand from 810 to 860 kv with a factor of safety, in the order of that for the 60-cycle test. In order to see what values might be obtained with steep-front tests, the tests shown in Table IV were made with a wave rising at a rate of 1,000 kv per microsecond for gap lengths up to 33 inches.

Above 33 inches, some rounding of the applied wave was experienced, and experience shows that the test severity is reduced. No failure, however, occurred on these tests in the winding or to ground, which would indicate that deterioration, due to testing should not be greatly feared in this particular design. The model withstood 25 full waves at both

Figure 1 (left). Impulse tests on 667-kva 69-kv transformer

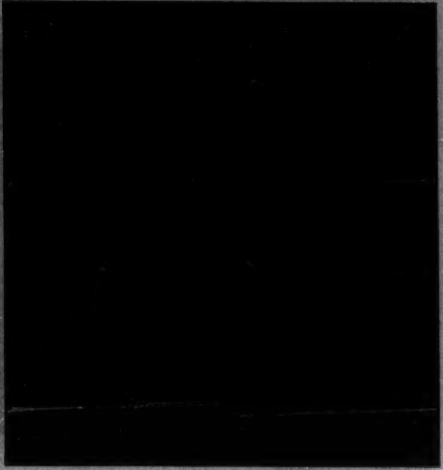

Figure 2 (above). Oscillogram of test on 138-kv transformer insulation

650 and 675 kv after these tests were made. A record of the steep front impulse test at 33 inches gap length on the model is shown on oscillogram *1144-65*.

Tests on a large 138-kv transformer which had to be rebuilt were made. Tests, not to failure, but which were under the "design level" at which failures might be expected were made. The results of these tests are shown in Table V. The required values versus the test values are shown in Table VI. The values given in these tables might be studied as before. If full waves of 650 kv only were required, probably some reduction in 60-cycle test voltage could be made, since it is believed that the 925-kv wave could have been held as a full wave provided the bushing had not flashed over. If a reduction in 60-cycle strength is not made, the winding strength alone could be reduced, and the unit would not be internally co-ordinated. Co-ordination is highly desirable.

If we retain present levels, the user who depends on gap protection alone is reasonably safe. Further, if a lightning arrester is used and is subject to undue currents or rates of rise, some transformer failures will be averted.

Present failure rates are extremely low, which indicates that excessive currents or rates of rise are very seldom met, or that some steep front transformer strength exists. Some years ago, transformers had two thirds their present full-wave levels, no lightning arrester protection and no steep front strength and relatively few failures occurred. Perhaps, therefore, the number of failures would not be changed if the full-wave strength and test of transformers were barely met, when lightning arresters are used.

Lines are now designed where there are practically no lightning failures. Stations can be so well protected that very low currents result. Perhaps the lightning arrester characteristics can be entirely relied upon in transformer design, and then it would seem definite that steep front strength is unnecessary, and reductions in 60-cycle strength and steep front strength could be made provided the standards would permit.

The following proposals might be made:

1. For the full waves now specified, make a new 60-cycle test somewhat lower and drop the chopped-wave test and reduce the steep-front test.
2. Retain approximately the present full-wave and steep-front test.
3. Have a full-wave test only.

Conclusions

Test results have been shown which indicate the impulse strengths of transformers compatible with the 60-cycle insulation strength. This information is useful in considering the highest values obtainable for use in co-ordination studies.

Depending on the degree of co-ordination, it is possible to reduce some of the insulation tests of transformers. It is believed that this subject should be considered in two groups for oil insulated power transformers. These are transformers from 15 to 69 kv and from 115 kv up.

It would be recommended that the standards for the first group be changed as follows: Add the NEMA steep-wave tests to the ASA standards, and eliminate the chopped waves. If acceptance tests were to be required by the standards, like the present 60-cycle tests, only the full-wave tests, consisting of full waves as specified now, might be used. The requirements for the second group are not as clear. It would seem that a reduction in 60-cycle strength, and in the NEMA steep-front test could be made, dropping the chopped-wave test, and retaining the present full-wave tests. Those using gap protection only would require the present higher grade of insulation.

Table V. Tests on Transformer*

Type of Test	Number of Tests	Gap Length, Inches	Oscillogram	Kilovolts
Steep front	7	$30^{1}/_{2}$		
Steep front	10	32	*1144-66*	1,090
Chopped waves	5			875
Chopped waves	4		*1144-68*	925
Full wave	1		*1144-67*	650

* No failures occurred on these tests.

Table VI. Comparison of Required and Test Values, 138-Kv Insulation

Type of Test	NEMA or ASA Standard	Kilovolts Required	Kilovolts Withstood	Gap Length, Inches	
				NEMA	Actual
Steep front	NEMA	960	1,090	29*	32
Chopped wave	ASA	750	925		
Full wave	ASA	650	650		

* The equivalent gap length for 960 kv and 0.96 microsecond is not given, but is estimated to be in the order of 27 to 29 inches.

Discussion

J. R. Meador (General Electric Company, Pittsfield, Mass.): Mr. Vogel has written a paper on a subject that deserves a great deal of thought and discussion. The question of what types of impulse waves to use in test, and what their relative voltage levels should be, is very important to the industry. It is this importance that leads me to question some of the actual and implied conclusions.

In testing a developmental transformer, coil stack, or insulation structure, it is obviously desirable to get as much data as possible. We have to be careful, however, to distinguish between proof-testing a new proposed design and getting data for a revision of existing standards.

This is exemplified by the maximum voltages applied to the high-voltage winding of the 667-kva transformer, which were as follows:

Full wave, 472 kv—failed
Steep wave, 833 kv—did not fail
Chopped wave, 418 kv—did not fail
60-cycle, 160 kv—did not fail

These tests demonstrate what this particular transformer will withstand on the different types of tests but they certainly do not show what the strength of the transformer is, except on the full wave. Even the full-wave strength may have been affected, for example, by incipient damage during the steep-wave tests.

None of the tests show the 60-cycle breakdown strength. How can it be concluded then that the present ratio of 60-cycle test to full-wave test should be changed? The same applies to all of the other relative voltage levels.

I have one comment on the author's various proposals for possible future tests. It concerns the substitution of steep waves for the present chopped waves. Without discussing the merits of the change so far as stress on the transformer is concerned, there is one argument that should not be overlooked. It is well known that internal winding failures, such as those that might be caused by chopped waves or steep waves, will often regain much of their original strength if permitted to soak in oil for a short period. It is essential therefore that the final full wave (and neutral current) oscillograms be taken as soon as possible after the application of the steep tailed waves. This is easy to do in the case of the chopped wave. When steep waves are applied, a change in connection of the impulse generator is often required before the remaining tests are made. In this case the interval may be long enough to prevent detection of the failure.

E. R. Whitehead (Illinois Institute of Technology, Chicago, Ill.): Mr. Vogel's paper illustrates the feasibility of designing modern power transformers to meet the NEMA steep-front impulse tests with suitable margins, and recommends that future standards for transformers of 69 kv and lower voltage rating include these requirements as design, if not acceptance, tests. For the higher voltage classes of 115 kv and above the possible reduction in winding strength is pointed out.

I should like to comment in support of Mr. Vogel's view that transformers up to and including the 69-kv ratings be designed to meet steep-front tests at or near the present NEMA levels even if the steep-front tests are not included in the standard acceptance tests. I believe it is well understood that factors of line impulse insulation, ground wire protection (or lack of it), structure footing resistances, and the type and location of lightning protective devices are much more variable on the lower voltage than on the higher voltage systems for which the best system design practices are more easily justified economically. Experience indicates that this variability contributes to the relative importance of steep front waves of magnitude substantially greater than that established by the standard tests on lightning arresters.

For the higher voltage classes, perhaps 115 kv and above as suggested, it seems logical to take advantage of the factors of good ground wire protection, low structure footing resistance and transformer-mounted lightning arresters and establish winding strengths more directly dependent upon the protective levels set by the lightning arresters. The cost of providing adequate insulation is a factor of greater importance in the high voltage classes than in the lower.

It has been the writer's experience over many years of association with impulse testing of transformers that defects in material or workmanship are detected much more frequently than are errors in design. Based on this experience, it might be concluded that steep-front design tests should be made to check each new design, and that full-wave tests be employed as the normal acceptance tests.

Wm. L. Teague (Westinghouse Electric Corporation, Sharon, Pa.): In his paper, Mr. Vogel has presented some interesting data. His comparisons of the relative severity of steep-front, chopped-wave, and full-wave tests are based on a few specially designed units. An evaluation of the relative severity of tests with the three types of waves also can be made by considering the results of commercial impulse tests on a large number of transformers.

The results of impulse testing 500 power transformers over a period of 15 months were analyzed. All of these transformers were designed to withstand front-of-wave, chopped-wave, and full-wave tests. Although some of the designs were for special levels and some of the tests varied from standard, these variations were relatively small and kept at a constant proportion for the three types of waves. Of the 500 units tested approximately 300 were given front-of-wave and full-wave tests; 100 were given chopped-wave and full-wave tests; and the remaining 100 were subjected to front-of-wave, chopped-wave and full-wave tests. This would mean that all 500 units were subjected to full-wave tests, 400 to front-of-wave tests, and 100 to chopped-wave tests. The faults revealed by the three types of tests expressed as a percentage of the total units that received the test were essentially the same. Hence, in the commercial impulse testing of power transformers in large numbers the front-of-wave, the chopped-wave, or the full-wave test was equally searching in its effect.

The results of these tests also indicate that the volt-time characteristics of transformer insulation as defined by NEMA front-of-wave tests and ASA chopped- and full-wave tests are approximately correct.

Since both the front-of-wave test and the chopped-wave test stress the turns, coils, and major insulation at the line end of the winding, it is not necessary or economical to apply both types of waves in the commercial testing of transformers. Either type of wave should be sufficient to verify that the windings will withstand flashovers and have the required short-time strength level. Of the three types, the full wave comes nearest to being a complete test. It constitutes a reasonable test on the line end of the winding up to full-wave levels and demonstrates the dielectric strength between interior parts of the winding and to ground where voltage stresses may result from oscillations. Hence, in the commercial impulse testing of transformers some form of chopped wave and the full wave are essential. The trend in impulse testing should be toward simplifying and streamlining the tests.

Philip Sporn and **I. W. Gross** (American Gas and Electric Service Corporation, New York, N. Y.): This paper apparently suggests the reduction of severity of dielectric tests on transformer insulation, and bases the suggestion largely on "results of some tests made in the development of a possible new line of transformers." The author seems to imply that there is a relation between the 60 cycle and impulse strength of transformers. This is a philosophy which we thought was entirely abandoned over 15 years ago based on experience with designs prevalent at that time. The basis for the 60-cycle test values for transformers which has been unchanged for more than 30 years has given such a good account of itself under service conditions, that any attempt to change it at this time should be made only after the fullest consideration of the fundamentals of transformer design and the expected over-voltages in service. Of course, this assumes that impulse requirements will be independently handled.

As to impulse strength and test values, the present basic insulation levels are based on so solid a theoretical foundation and on so much practical experience that no attempt should be made to change them except on clear indication of the soundness of the new course.

When the impulse testing of transformers was being developed nearly 20 years ago on a commercial basis, various ideas were held on the required severity. As fundamental analysis progressed and more became known about the types of impulse surges to which transformers in service could be subjected, and as the impulse design problem in transformers was better understood, the thinking in our own company developed along these lines: It was believed that transformers in service could be subjected to three different types of impulse or surges of lightning origin: first, a full-wave impulse without alteration by reason of gap flashover or lightning arrester action; second, a chopped wave where the chop took place on the wave tail; and third, a chopped wave where the chop took place on the front of the wave. The reasons why such surges could reach a transformer are now too well known to require further comment. The initial impulse testing of transformers used the full wave, supplemented by a chopped wave which was representative of conditions obtaining when the bushing (air gap) flashed over.

For the third condition, that is, flashover on the front of the wave, we requested and received commercial impulse tests on transformers with a steep front in the order of 1,000 kv per microsecond, flashover taking place on the front.

The ability of transformers as far back as 15 years ago to withstand such waves was amply demonstrated by commercial factory tests, and the successful operation of such transformers under impulse conditions, on our own system at least, has given ample justification for continuing these types of tests up to the present time. It is not clear from the author's comments whether he questions the ability of transformers built within the last 15 years or so of withstanding all three types of wave—full wave, chopped wave, and fast front. Neither is it clear why he believes the transformers on which he has reported impulse tests are superior to those which have been built within the past 15 to 18 years.

The general pattern of impulse testing today is for the transformer to be made to withstand a full wave of the basic impulse insulation class together with a chopped wave, the chop taking place on the tail at 115 per cent of the full wave, and a fast front test with the crest value being in the order of 150 to 200 per cent of the full-wave value, depending on the transformer voltage class. As mentioned before, present-day transformers are capable, as demonstrated by commercial tests, of withstanding these test values.

We are in thorough agreement with the author that if we required only a full-wave test on the transformer insulation it would result in a lower impulse strength of transformer insulation. If, as he predicts, and we concur therein, some transformer failures would develop if the impulse tests were limited to full waves, such a proposal should be considered all the more carefully in the light of the over-all economic penalties attendant upon failure. It does not seem to us that with the existing background such a procedure would be at all attractive.

The author states that it is believed "the windings should be stronger than the insulation to ground." Further amplification of this statement is certainly desirable. We consider a transformer as a unit, and whether it fails between turns or to ground is beside the point. A failure is a failure, and if there is a service interruption by reason of a failure, it is of little concern whether that failure took place between turns or sections, or to ground.

There does seem to be some point in eliminating the so-called chopped-wave test and substituting therefor the front-of-wave test. After all, the three tests which are now required on our system transformers merely determine three points on the volt time co-ordinates of the transformer insulation curve. To omit the chopped-wave test (not fast-front test) could probably be tolerated without any appreciable sacrifice of transformer quality.

The proposal of the author that the acceptance test of a transformer so far as impulse is concerned be limited to the full-wave test would leave us in the position where we know nothing about the short time impulse strength of the transformer. We certainly do not want to face this situation now or in the future.

There seems to be some implication in the author's paper that he favors the use of an air gap as a protective device for a transformer. If the transformer is built with insulation sufficiently above the test level of the gap, there certainly is no objection to this, provided the user is willing to live with the service outages that are inherent in such protection. However, we are firmly convinced that the fundamental insulation requirements of a transformer should be such that it will perform successfully without service interruption when protected by the modern lightning arrester which has given such a high degree of reliability as proved by experience obtained in service during recent years.

P. L. Bellaschi (Consulting Engineer, Sharon, Pa.): This discussion has reference to the economics of power transformers, especially from the application end. First, in regard to the insulation: "Does the present structure of tests provide a balanced and economical design in modern transformers?" My answer is "yes." These are the principal reasons. The volt-time characteristics embodied in present ASA impulse tests and NEMA front-of-wave tests are fundamentally sound, economically attainable, and well co-ordinated with available methods of protection. Whether the chopped wave is retained or dropped would not change the picture fundamentally. Presumably if the chopped wave is dropped, the front-of-wave would be substituted in its place in the tests.

On 230-kv stations designed with overhead ground wire over the station structure and extended for at least one-half mile on the line, as is now the practice, the modern lightning arrester provides co-ordinated protection to the full-wave strength of transformer insulation, for lightning arrester discharge current well up to the values so far experienced in these stations. The higher voltage, front-of-wave transformer tests in present standards provide for the necessary strength to withstand the stresses such as can result from short-time effects due to lead drops, and so forth, as are entailed from rapid impulses. Similar conclusions regarding present full-wave and short-time tests apply even more so for the low and medium voltage substations, for in these applications higher discharge currents prevail and lead drops can assume relatively greater importance.

Looking to the future, to the rationalization process in course, we shall soon be dealing with reduced insulation more and more, especially in applications to high-voltage grounded systems. In fact on well-grounded systems at the higher voltages, 230 kv and above for instance, we shall be dealing quite commonly with 75 per cent and even 70 per cent insulation levels.

In speaking of well-grounded systems, I have reference to systems in which dynamic overvoltages to ground on the unfaulted phases do not exceed 65 to 70 per cent line-to-line voltage or even lower. That is, where X_0/X_1 is less than one and R_0/X_1 is under a quarter or thereabout. Equally import, overvoltages resulting from load dropping and runaway of hydro machines, as well as surges due to restrikes of circuit breakers, all are within proper and acceptable limits by design and operation.

Under these conditions on these systems, 75 per cent and possibly 70 per cent lightning arresters can be safely applied. In these applications the basic insulation levels of transformers especially would be proportioned accordingly with corresponding economies, not to mention other advantages such as in the improved electrical characteristics of the equipment proper and relative reduction of physical size. These practices are currently in full course of development and mark another milestone in the economies attainable, in keeping with sound engineering, through the process of rationalization of co-ordination and protection of station insulation.

F. J. Vogel: My paper as written was intended to raise questions regarding present insulation standards in the design of transformers, particularly as to whether; first, the relations of steep-front full-wave and 60-cycle tests are correct; second, if the present levels up to 69-kv class are desirable; third, if steep front values are required; and last, if reductions in the test values for the higher voltage classes are in order.

With respect to the first question, it seemed to be the opinions of both Mr. Teague and Mr. Bellaschi that they are. Mr. Meador questioned it on the basis of lack of test data, referring to the fact that the 60-cycle breakdown value was not given. However, its insulation to ground was very similar to that referred to in many previous papers, where the impulse ratio was about two, which would indicate that the 60-cycle strength would not be greatly in excess of the 160-kv cited. Please note that the value of 472 kv was obtained using oversize bushings and it is apparent that if no 60-cycle tests were required, and full-wave impulse tests only were required, a large decrease in insulation clearances and materials could have been made.

The second question is answered only by Mr. Whitehead, who agrees with me that the present levels for transformer insulation up to the 69-kv class are desirable without change.

The question regarding steep front wave strength is not so directly answered and has a number of ramifications. Both the discussions of Mr. Whitehead and Mr. Sporn and Mr. Gross indicate that that feature is required. I would like to point out that the ability to meet the chopped wave does not imply ability to meet steep front waves, although the converse is likely. This means that the basic insulation levels alone do not ensure an adequate transformer, and that the full waves and steep front waves probably do ensure the maximum values. The questions of difficulty in applying steep front tests, and even failure detection, were brought up by both Mr. Meador and Mr. Teague. I think further discussion of this is necessary.

With respect to the last question, there does seem to be agreement that reductions for the higher classes are possible, on the basis of lightning arrester applications. Mr. Whitehead and Mr. Bellaschi are in agreement, and I know that the practice is being given serious consideration elsewhere.

The discussion by Mr. Sporn and Mr. Gross would seem to merit some further reply. I wish to thank them for a most constructive discussion. My reply to their discussion is as follows: They raised the question as to a relation between 60-cycle and impulse strength of transformers. Fifteen years ago there was no relation between the 60-cycle and impulse strength of transformers. It was just a little bit like the question of the members of the human race. You could say that all men were members of the human race but you could not say that the human race were all men. Likewise transformers are composed of major insulation to ground and winding insulation. The impulse strength to ground was found to bear a fairly definite relation to the 60-cycle strength. If the winding insulation were made equal to it then it also would bear this fixed relation, and this fixed relation would be the best which you could obtain compatible to the 60-cycle strength. I have no objection to the present basic insulation levels as applied to operating voltages, particularly up to 69 kv. I question very much that they are based on a very exact foundation, but they certainly have given a good practical account of themselves.

I am in complete agreement with the discussors' thinking with respect to the three different types of impulse. That there will be full waves is beyond question and that the voltage may be high enough to cause a flashover adjacent to the transformer also seems to be a possibility. This may definitely take place on the wave tail or on the front of the wave.

It is very likely that the paper was not clear with respect to proposals made by me, but the fact is that I intended to raise questions rather than to give my viewpoints. I believe that full-wave and either chopped- or steep front-wave tests should be given to nearly all transformers. It was proposed by some members in the Transformer Committee that chopped waves might be eliminated and full waves be used only. It is clear from the discussion that we both agree that full waves alone are inadequate.

There are a number of other questions which can be lumped together. Were the transformers 15 years ago just as good? Why should the winding be stronger than the insulation to ground? Why favor the use of some form of limiting gap as a possible protection device? The answers to these questions are as follows:

In two papers which I presented recently, methods of obtaining the strength between coils and in determining the difference in effect between steep wave-front tests and chopped-wave tests were derived. So far as I know this is the first line of transformers which were laid out using these data. A study of the values given in the paper show that very high impulse strengths were obtained and that broad gaps sufficiently long to avoid trouble with switching surges could probably be used.

The NEMA steep front tests as at present constituted are less severe than the tests using the gaps specified by one user and which can easily be made based on the performance of these transformers.

It is true that the transformer's insulation strength so far as the user is concerned is a unit. However, if the transformer winding is strong enough, the transformer's maximum strength as determined by the major insulation is obtained. I believe that a slight margin in the winding above this should be taken. Another reason is that there is an additional stress in the coil structure due to the fact that it is excited. Further, there is little or no extra cost in making the winding and major insulations equal.

There are two reasons why the use of a gap as an auxiliary protection device might be desirable. One is that for one reason or another the lightning arrester may not do its duty; or the lightning arrester may not be used for economical or other reasons. Another reason is that tests made by the author on several occasions have shown that with man-made lightning, it is possible to obtain excessive voltages even with lightning arresters present. I do not think that this is any argument against the use of lightning arresters since they prevent outages and possibly give an extra margin of protection. Nevertheless if there is a gap which can ordinarily be protected by the lightning arresters, and will always protect the transformer, I see no objection to it.

A Method for Designing Pulse Transformers

H. S. KIRSCHBAUM
ASSOCIATE AIEE

C. E. WARREN
ASSOCIATE AIEE

THE RAPID development in recent years of circuits and techniques employing short-duration pulses of voltage and current has created considerable interest in the use of transformers as coupling devices under pulsed conditions. The pulse transformer will perform one or more of the following functions with a minimum of distortion to the transmitted pulse:

1. Impedance transformation.
2. Voltage and current transformation.
3. Phase inversion.
4. D-c isolation of two or more circuits.

This paper will describe a method for designing pulse transformers, coupling linear resistive source and load impedances with either step-up or step-down turns ratio, nonphase inverting. The design procedure will be concerned largely with controlling wave form on the front and top of the output pulse. Other features of the wave form, transformer size, rating, and efficiency may be adjusted within certain limitations.

Some Fundamental Considerations

In order to design a pulse transformer to give a specified performance in a particular circuit, it is necessary to determine the transformer parameters which significantly affect the over-all performance of the circuit. Since the pulse transformer is required to transmit wave forms which are essentially transient in character, it is evident that the distributed capacitances of the transformer will play an important part in determining the transformer performance. In fact, a rigorous approach to the problem would involve a consideration of the electric and magnetic fields within the transformer in terms of Maxwell's equations. This approach, however, is much too general and cannot be handled in cases of practical interest. The first step in the simplification of the problem, therefore, is to approximate the fields in terms of lumped circuit parameters.

Figure 1 (A) shows a simplified transformer illustrating the several physical quantities usually considered in pulse transformer theory. These quantities may be classified in terms of the magnetic and electric field energies as follows:

1. Magnetic energy stored in the mutual flux field Φ_m, within the transformer core.

2. Magnetic energy stored in the leakage flux fields Φ_1 and Φ_2. This energy is usually considered as residing in the space between primary and secondary windings.

3. Electrostatic energy stored in the capacitance network of the transformer. The capacitance network illustrated consists of the capacitances of the individual turns to the core, capacitance between adjacent turns on the same winding and capacitance from primary to secondary turns.

The simplified transformer shown in Figure 1 (A) is still too complicated for convenient analysis and is usually simplified by means of the following assumptions:

1. The energy stored in the capacitance between adjacent turns on the same winding is small and therefore these capacitances are usually neglected.

2. The energy stored in the distributed winding-to-core and winding-to-winding capacitances is considered to be stored in equivalent capacitances connected to the coil terminals. See Figure 1(B). A primary and secondary terminal of like polarity are at the core potential either conductively or pulsewise.

In Figure 1 (B), the equivalent capacitances C_{pe} and C_{se} will store the same energies respectively as would be stored in the distributed primary and secondary winding-to-core capacitances of the actual transformer. The capacitance C will store the same energy as would be stored in the distributed primary-to-secondary capacitance of the winding. The equivalent capacitances as defined are usually calculated[1] on the assumption of a linear distribution of voltage along the coil. A detailed analysis of circuits similar to that of Figure 1(A) shows that the assumption of linear voltage distribution is in error during the initial part of the transient period. However, experience has shown that for the usual circuit applications, the higher modes of oscillation in the transformer are well damped and do not affect over-all circuit performance. In some cases the initial nonuniform distribution of potential along the coil may overstress the turn-to-turn insulation of the coil.[2]

A Pulse Transformer Equivalent Circuit

The circuit of Figure 1(B) may be replaced by the equivalent circuit of Figure 2(A) where L is the transformer leakage inductance and the shunt branch is a circuit taking into account the pulse excitation properties of the transformer core. The circuit of Figure 2(A), in turn, may be replaced on a one-to-one, primary basis by the equivalent circuit[3] of Figure 2(B).

The design procedure described in this paper is based on the transformer equivalent circuit of Figure 2(B). This circuit differs from others[1,4] which have been used as a basis for pulse-transformer design in that the capacitance, nC, shunting

The work described in this paper was performed under contract between the Air Materiel Command, Watson Laboratories, Cambridge (Mass.) Field Station, Cambridge, and the Ohio State University Research Foundation, Columbus.

The authors wish to acknowledge the assistance of Neal Smith and Leo Botwin in obtaining and preparing the data used in this paper.

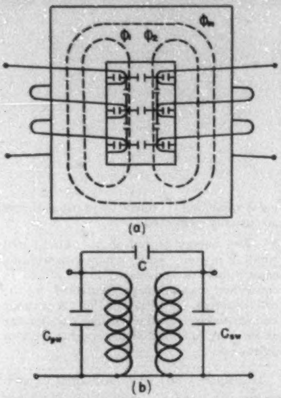

Figure 1. (A) Schematic diagram of transformer showing capacitance network and magnetic fluxes

(B) Simplified transformer circuit showing reduction of capacitance network to equivalent terminal capacitances

the leakage inductance, L, has been retained as an essential part of the circuit. The circuit is not unique or complete, but it has been found to be adequate for the design of transformers with turns ratios, n, in the range of about 1/10 to 10, but not in the vicinity of n equals one. In some cases, the design of unity turns-ratio transformers requires consideration of higher modes of oscillation and, therefore, a more complicated equivalent circuit.

The circuit parameters in the equivalent circuit of Figure 2(B) may be related to the design parameters of the transformer by simple analytic expressions. It has been found that a wide range of practical designs may be realized in terms of a simple 2-layer concentric-coil winding; therefore, only this type of winding design will be described in this paper. The design equations and properties of other types of windings are described in reference 1. The leakage inductance, L, and effective interwinding capacitance, C, of the 2-layer, concentric-coil winding are given in the following equations:

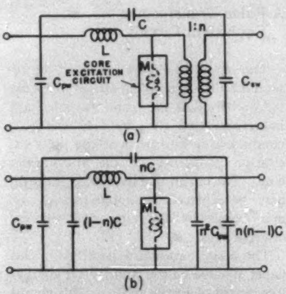

Figure 2. (A) Transformer equivalent circuit before reduction to one-to-one primary basis (B) Transformer equivalent circuit reduced to one-to-one primary basis

$$L=b\frac{4\pi N_p^2U}{d}\left(\Delta+\frac{a_1+a_2}{3}\right)10^{-9}\text{ henries} \qquad (1)$$

$$C=\frac{0.0885\,kdU}{3\Delta}10^{-12}\text{ farads} \qquad (2)$$

The shunt core-excitation circuit shown in Figure 2(B) may assume a variety of forms[5] depending on the problem under consideration. For the purposes of this paper, the core-excitation circuit will be considered as a single shunt inductance, M, related to the design parameters by the following equation:

$$M=\frac{4\pi N_p^2A}{10^9l}\mu_e\text{ henries} \qquad (3)$$

The effective pulse permeability, μ_e, usually is determined experimentally for a particular core material and takes into account eddy-current and hysteresis effects, in addition to the usual excitation ampere-turns. Pulse permeability depends on pulse duration, maximum flux density change, lamination thickness, and the magnetic and resistive properties of the core material. A complete discussion of core-excitation phenomena during pulse excitation is long and involved and the reader is, therefore, referred to reference 1 for a more detailed treatment of this subject.

Equivalent Circuits for the Step-Up Transformer

The complete primary-basis equivalent circuit of the step-up pulse transformer, coupling resistive primary and secondary impedances, and including external, shunt, primary and secondary capacitances, C_p and C_s, is shown in Figure 3(A). The secondary impedance, R_s, and external shunt capacitance, C_s, are secondary parameters referred to the primary by the square of the turns ratio. Examination of the expression for the total primary shunt capacitance, C_3, shows that the transformer introduces a term which is negative for turns ratios greater than one. Unless an abnormal amount of external shunt primary capacitance is present, C_3 is small and may be neglected in the design procedure.

For purposes of analysis, it is practicable to divide the transmitted pulse into three parts, consisting of: the rising front and subsequent damped oscillation, if present; the sloping top of the pulse; and the tail or subsidence transient. This division is based on the assumption of a rectangular pulse input (see Figure 4). The pulse front is represented very well by the equivalent circuit of Figure 3(B), which omits the excitation branch.

δ = pulse duration, seconds
τ = per unit pulse rise time, t_0/T
μ_e = effective pulse permeability
λ = derivative operator

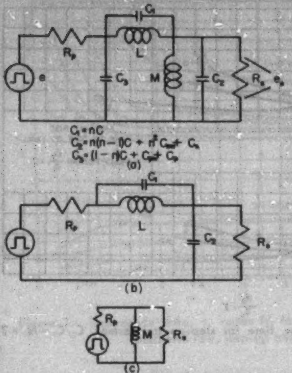

Figure 3. (A) Complete primary-basis equivalent circuit of step-up transformer and terminations
(B) Equivalent circuit for analyzing front of pulse
(C) Equivaent circuit for analyzing top of pulse

For the pulse top, only the excitation branch and terminating impedances are of importance and the transformer may be represented by the equivalent circuit of Figure 3(C). The equivalent circuit for the pulse tail in general involves all the circuit elements, including a more elaborate representation of the excitation circuit. For many practical applications the wave form of the pulse tail is not important or at least the wave forms resulting from the proposed design procedure are tolerable. A detailed discussion of this matter will be found in references 1 and 4.

Design of the Step-Up Transformer

The design procedure which is described in the following paragraphs provides a means for controlling the shape of the transmitted pulse on the front and top of the pulse. The design procedure is based on the assumption that the equivalent circuits of Figure 3 adequately represent the pulse transformer and that the behavior of these circuits, for perfect rectangular pulse input, represents all possible wave forms for the transmitted pulse for a given set of circuit conditions. The design then is carried out in three main steps.

1. For a given set of circuit conditions and turns ratio, to determine the transformer parameters L and C which give a satisfactory wave form, particularly on the pulse front.
2. Construct a transformer with the required turns ratio and the L and C parameters as determined in step one.
3. Adjust the design until proper performance on the top and tail of the pulse is obtained.

Since only a limited range of pulse wave forms may be obtained, with perfect rectangular pulse input, it will be possible to define certain salient features of the transmitted pulse and incorporate these factors into the design procedure. With reference to Figure 4, three features of the pulse wave form are defined as follows:

1. The time t_0 for the pulse to rise to 90 per cent of the flat-top pulse voltage; that is the voltage which would be obtained if the transformer were ideal.
2. Amount of overshoot expressed as a percentage of the flat-top pulse voltage.
3. Amount of droop, D, which is the deficiency in pulse top voltage at the end of the pulse duration, δ, expressed in per unit of the flat-top pulse voltage.

The first two of these wave-form specifications are related to the pulse front and may be determined with the aid of the circuit of Figure 3(B). This circuit contains five independent parameters, and the determination of values of the two performance specifications for all possible combinations of these parameters would be a formidable task. However, consideration of the differential equations of the circuit shows that the performance of the circuit depends on only three dimensionless ratios of the five parameters and the definition of an arbitrary unit of time. These ratios which are derived in Appendix I are listed for reference:

Base unit of time, $T = 2\pi\sqrt{LC_2}$

R_p/R_s

R_p/Z_0 (where $Z_0 = \sqrt{L/C_2}$)

C_2/C_1

The determination of rise time, t_0, and per cent overshoot for a wide range of the above dimensionless parameters was made by means of a transient analyzer.[6,7] A typical set of these data for $C_2/C_1 = 7$ is shown in Figures 5 and 6. It is not possible to include all the data in this form because of space limitations. However, since an output wave form with zero per cent overshoot is desirable in many applications, Figures 7 and 8 have been prepared giving data in terms of per unit rise time, $\tau = t_0/T$ and $R_p/Z_0 = \gamma$ versus the ratio, $C_2/C_1 = N_1$ for several values of R_p/R_s and for zero per cent overshoot. Similar curve sheets for other values of per cent overshoot may be plotted from a complete set of basic data as illustrated by Figures 5 and 6.

It should be noted here that there are two values of the ratio γ for which zero per cent overshoot occurs with particular values of the ratios, R_p/R_s and N_1. These two values of γ will be referred to as zero per cent overshoot, low, or zero per cent overshoot, high, meaning the low or high value of γ for a particular set of values for the ratios, R_p/R_s and N_1. The occurrence of two critically damped points in the response of the circuit of Figure 3(B) is particularly interesting in that it makes possible two alternative designs for a particular set of specifications. This matter will be discussed later in the paper.

At this point, it is possible to find the two winding constants L and C in terms of fundamental specifications of the pulse wave form and external circuit parameters.

The two quantities τ and γ may be written as follows:

$$\tau = t_0/2\pi\sqrt{LC_2} \tag{4}$$

$$\gamma = R_p/\sqrt{L/C_2} \tag{5}$$

where $C_2 = n(n-1)C + C_{os}$ and $C_{os} = C_s + n^2C_{ms}$. From equations 4 and 5

$$L = \frac{t_0R_p}{2\pi\tau\gamma} \tag{6}$$

$$C = \frac{1}{n(n-1)}\left(\frac{\gamma t_0}{2\pi\tau R_p} - C_{os}\right) \tag{7}$$

The leakage inductance, L, and effective interwinding capacitance, C, may be found, provided the quantities in equations 6 and 7 are known. Of the several quantities involved, t_0, R_p, n, and an estimated value of C_{os} will be immediately available. The values of τ and γ may be found from Figures 7 and 8 for zero per cent overshoot, low or high, provided R_p/R_s and N_1 are known. The ratio, R_p/R_s, will be given as part of the fundamental specifications, but the proper value of N_1 remains to be specified. In order to determine N_1 in terms of fundamental specifications of wave form

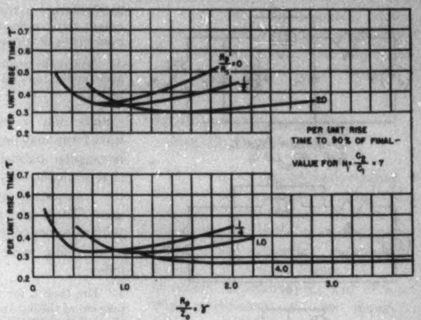

Figure 6. Per unit rise time for step-up transformer, $C_2/C_1=N_1=7$

and circuit parameters, the following calculation is made:

By definition

$$N_1=\frac{C_2}{C_1}=\frac{n(n-1)C+C_{os}}{nC}$$

Solving for C from the foregoing equation and using equation 7, the following equality is found

$$\frac{C_{os}}{nN_1-n(n-1)}=\frac{1}{n(n-1)}\left(\frac{\gamma t_0}{2\pi\tau R_p}-C_{os}\right)$$

When rearranged the foregoing equation becomes

$$\frac{t_0}{R_pC_{os}}=\left[\frac{2\pi\tau}{\gamma}\right]_{N_1}\frac{N_1}{N_1-(n-1)} \tag{8}$$

Equation 8 is implicit in N_1, since τ and γ are functions of N_1. The equation may be solved by assuming values of N_1, evaluating the term in square brackets from Figures 7 and 8, and plotting the left-hand side of the equation as a function of N_1. Figure 9 shows the result of such a calculation for zero and five per cent overshoot, both low and high, with $R_p/R_s=1$ and a turns ratio $n=5$. Data for five per cent overshoot are included to illustrate the relative difficulty of designing for specified overshoot at high and low values of γ.

It should be noted that the curves of Figure 9 are functions of several parameters. Additional curve sheets must be prepared if one or more of these parameters are changed. This is a matter of only a few minutes calculation, even when interpolation on Figures 7 and 8 is required. It is also interesting to note that the curves of Figure 9 define certain ranges of compatibility among the several specifications.

The values of L and C for the transformer to give a specified wave form for specified terminating conditions now may be calculated. For example, if $R_p/R_s=1.0$, $R_p=50$ ohms, $t_0=10^{-7}$ second, $C_{os}=700\times10^{-12}$ farad, zero per cent overshoot, high, then $t_0/R_pC_{os}=2.85$ and from Figure 9, $N_1=6.8$. From Figures 7 and 8, for the derived value of N_1, $\tau=0.38$ and $\gamma=2.10$. From equations 6 and 7, $L=10^{-6}$ henry and $C=50\times10^{-12}$ farad.

The next step in the design procedure is to determine from equations 1 and 2 and the required values of L and C, the significant dimensions of the transformer core and coils. The manner in which this problem is handled will be guided by the following considerations.

1. A lower limit on wire size is set either by current loading or by mechanical strength and ease of winding.

2. A minimum is set on the interwinding insulation thickness Δ by the transformer voltage and the dielectric strength of suitable insulating materials.

3. The mean coil perimeter, U, and coil length, d, must be chosen to fit one of a standard set of cores.

Equations 1 and 2 may be put in the following form

$$N_p^2U^2=\frac{3\times10^{21}}{4\pi\times0.0885}\,\frac{LC}{bk}\,\frac{\Delta}{\left(\Delta+\frac{a_1+a_2}{3}\right)} \tag{9}$$

$$d^2=\frac{12\pi10^3}{0.0885}\,\frac{N_p^2bC\Delta\left(\Delta+\frac{a_1+a_2}{3}\right)}{kL} \tag{10}$$

In one form of the design procedure, it is convenient to start by assuming an appropriate wire size, and a value for Δ at least as large as required by the transformer voltage rating and the dielectric strength of the insulating material to be used.

1. With the chosen values of a_1, a_2, and Δ calculate $N_p^2U^2$ from equation 9.

2. Select a core and its corresponding value of U^2 from Table I and calculate N_p. As a rule of thumb, limiting the ratio E/N_p to about 100 to 150 volts per turn, maximum will give a reasonable design. In Table I, values of U^2 are tabulated for several of the cores in a standard line. The value of U is based on a 1/16-inch clearance from core to mean coil perimeter all around. This clearance usually will prove satisfactory for values of Δ less than 60 mils. Tables of this sort for the standard lines of cores and for several values of clearance are extremely valuable in this design procedure.

3. With the value of N_p calculated previously, determine d from equation 10. The value of d must be such that the coil may be wound on one or both legs of the core with adequate creepage margin at the coil ends and the product of required secondary turns by the wire diameter, a_2, does not exceed d.

4. In case the required value of d is not satisfactory, steps 1, 2 and 3 must be repeated. Perhaps a core with a larger value of U may be used or Δ, a_1 and a_2 may be changed. In some cases, an insulating material with larger dielectric constant k, and dielectric strength must be used. In any event, equations 9 and 10 indicate the

several possibilities for effecting the proper change in design.

In the design procedure just described, a series of cuts and trys will lead to a choice of core, coil dimensions, and coil turns. However, two critical points arise in the design at step 3. The second of these points could be avoided if it were possible to find a relation such that the chosen wire diameter would just fill the required length, d, with the required number of secondary turns. Fortunately, such a relation can be developed. If the secondary and primary wire sizes are assumed to be equal, $a_1=a_2=a$, then equation 10 may be put in the following form

$$\frac{d^2}{a^2n^2N_p^{\,2}}=\frac{12\pi 10^8}{0.0885}\;\frac{\frac{\Delta}{a}\left(\frac{\Delta}{a}+\frac{2}{3}\right)bC}{n^2kL} \tag{11}$$

The denominator of the term on the left of the equal sign is just equal to d^2 if the wire diameter a includes an allowance for the winding space factor. Therefore, equation 11 gives the following relation when solved for Δ/a

$$\frac{\Delta}{a}=-\frac{1}{3}+\sqrt{\frac{1}{9}+\frac{0.0885}{12\pi 10^8}\,\frac{n^2k}{b}\,\frac{L}{C}} \tag{12}$$

Equation 12 determines uniquely the ratio of interwinding insulation thickness to wire diameter so that the secondary always may be wound with a single-strand closely spaced winding in the required coil length, d, with the required number of secondary turns. If the relation of equation 12 is satisfied, it will be necessary in step 3 to satisfy only the first requirement.

Equations 9 and 10 or 9 and 12 provide the starting point for designing a coil with circuit constants required to give a specified rate of rise and overshoot on the pulse wave form. There remains the problem of controlling the amount of droop on the pulse top. This characteristic sloping of the pulse top is due to the transformer exciting current flowing through the primary resistance, R_p. An approximate expression for the amount of droop, D, is derived in Appendix II and is given here for reference.

$$D=\frac{R_sR_p}{R+R_p}\,\frac{\delta}{M} \tag{13}$$

From equation 3 for the equivalent transformer magnetizing inductance and equation 13, it is found that the following inequality must hold if a specified amount of droop, D, is not to be exceeded.

$$N_p^{\,2}\mu_e>\frac{10^9}{4\pi}\,\frac{l}{A}\,\frac{R_pR_s}{(R_s+R_p)}\,\frac{\delta}{D} \tag{14}$$

It has been found convenient to design the transformer by means of equations 9 to 12 and then to check the droop requirements with equation 14. Equation 14 indicates the influence of the various parameters on droop and serves as a guide in altering a preliminary design.

The preceding discussion has described a design procedure for step-up transformers of the iso-type (that is, a transformer with isolated primary and secondary windings). Corresponding design equations for auto-type transformers are given in Appendix III.

Example of Step-Up Transformer Design

Assume the following transformer specifications:

1. Step-up iso-type transformer; $n=5$.
2. Primary resistance, $R_p=200$ ohms.
3. Primary-secondary impedance ratio, $R_p/R_s=1$.
4. Secondary external shunt capacitance, $C_{os}=75\times10^{-12}$ farads.
5. Pulse duration, $\delta=10^{-6}$ seconds.
6. Pulse front, $t_0=1/3\times10^{-7}$ seconds, zero per cent overshoot, high.
7. Pulse top, $D<0.05$.
8. Wire size number *33*; effective diameter, $a=0.0153$ centimeter.
9. Interwinding insulation, Kraft paper and oil; dielectric constant, $k=3.0$; dielec-

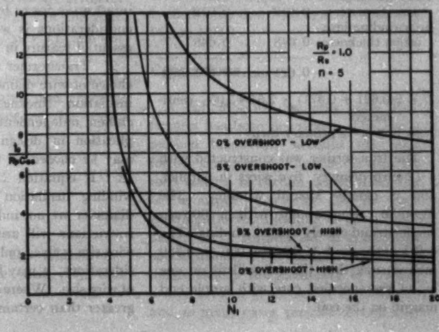

Figure 9. Graph of equation 8 for $R_p/R_s=1$, $n=5$

tric strength approximately 300 volts per mil.

10. Core, 2-mil Hypersil.

The first step in the design procedure is to find the proper values of L and C. From the specifications, $t_0/R_pC_{os}=2.22$, and from Figure 9, the required value of $N_1=8.5$. The proper values of τ and γ are found on Figures 7 and 8, and L and C are computed from equations 6 and 7, $L=1.36\times10^{-6}$ henry and $C=3.40\times10^{-12}$ farad.

This transformer will be constructed with a single-strand closely spaced secondary; therefore, the ratio, Δ/a, may be found from equation 12. The inductance correction factor, b, is assumed equal to one.

$$\frac{\Delta}{a}=-\frac{1}{3}+\sqrt{\frac{1}{9}+\frac{0.0885}{12\pi10^3}\,\frac{25\times3}{1}\,\frac{1.36\times10^{-6}}{3.4\times10^{-12}}}$$

$$\frac{\Delta}{a}=8.07$$

$a=0.0153$ centimeter or 6 mils
$\Delta=0.123$ centimeter or 48.4 mils

From equation 9, the core primary-turns factor, $N_p^2U^2$, is computed as follows

$$N_p^2U^2=\frac{3\times10^{21}}{0.0885\times4\pi}\,\frac{1.36\times3.4\times10^{-18}}{3.0}\,\frac{0.123}{0.133}$$

$$N_p^2U^2=3.85\times10^3$$

At this point, a cut-and-try procedure to select primary turns and core is employed. Only the correct try will be shown here. Use of the values of U from Table I will facilitate this procedure. It is found that core number *1356254* is about right. Allowing 1/32-inch clearance over-all on the core dimensions, so that the coil will slip over the core, an exact value of U is calculated as follows:

Core dimensions:	0.500 inch	0.250 inch
Clearance:	0.031	0.031
Twice primary to core insulation thickness:	0.030	0.030
Twice primary wire diameter:	0.012	0.012
Interwinding insulation thickness:	0.048	0.048
	0.621 inch	0.371 inch

$U=2(0.621+0.371)\times2.54=5.05$ centimeters
$N_p=12.3$ or 12 primary turns

The transformer was constructed with a 12-turn primary, five wires in parallel, and a closely spaced winding. The secondary was wound with a 60-turn single-strand closely spaced winding. The coil length, $d=5\times12\times0.006=0.360$ inch is such that the coil will fit on one leg of the specified core with ample end margin on the coil.

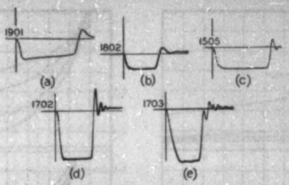

Figure 10. Oscillograms of output wave forms of step-up and step-down transformers constructed according to the proposed design procedure

(A) Zero per cent overshoot, high, $n=5$, $R_p=200$, $R_p/R_s=1$, $C_{os}=75\times10^{-12}$, $t_0=1/3\times10^{-7}$, $\delta=10^{-6}$

(B) Zero per cent overshoot, low, $n=1/5$, $R_p=312$, $R_p/R_s=1/4$, $C_{op}=5\times10^{-12}$, $t_0=10^{-7}$, $\delta=10^{-6}$

(C) Zero per cent overshoot, low, $n=2$, $R_p=50$, $R_p/R_s=1$, $C_{os}=56\times10^{-12}$, $t_0=10^{-7}$, $\delta=10^{-6}$

(D) Zero per cent overshoot, low, $n=5$, $R_p=50$, $R_p/R_s=1$, $C_{os}=175\times10^{-12}$, $t_0=10^{-7}$, $\delta=10^{-6}$

(E) Zero per cent overshoot, low, $n=10$, $R_p=20$, $R_p/R_s=1$, $C_{os}=700\times10^{-12}$, $t_0=2\times10^{-7}$, $\delta=10^{-6}$

The transformer was constructed according to the foregoing design, and bridge measurements of L and C gave $L=1.35\times10^{-6}$ henry and $C=5.8\times10^{-12}$ farad. The output pulse of the transformer is shown in the oscillogram of Figure 10(A).

Further Aspects of the Design Procedure

There are several features of the design procedure which should be emphasized at this point.

1. The method is basically a means for controlling certain features of the output pulse wave form resulting from a perfect rectangular input pulse. The qualitative correlation of response to other types of input wave forms by frequency spectrum considerations is well known and is an essential feature in the design procedure.

2. Transformer rating is fixed by the choice of wire diameter and interwinding insulation thickness. They may be chosen independently, with some complication in design procedure, or they may be chosen on the basis of equation 12. If equation 12 is used the interwinding insulation thickness and wire diameter are not independent and certain restrictions will arise. If, for example, wire size is fixed only by mechanical considerations, Δ may be adjusted by choice of wire size. Where Δ and a must both be greater than certain minimum values, it may be advantageous to have some control over the ratio, Δ/a. This may be accomplished in two ways.

Firstly, there is usually freedom in the choice of the zero per cent overshoot point for either low or high values of γ. The choice of low values of γ will result in larger values of the ratio, Δ/a, than the choice of the corresponding high value for γ. Secondly, for a particular choice of γ, high or low, the ratio, Δ/a, may be varied by properly adjusting the value, N_1. Figure 9 shows that N_1 depends on the ratio, t_0/R_pC_{os}. It may be possible to change one or more of these basic specifications to achieve a required ratio, Δ/a. For example, on the zero per cent overshoot, high, curve of Figure 9, decreasing t_0 results in an increase in the required value of N_1. Calculation will show that this procedure increases the ratio Δ/a, other factors being held constant. It is also true that the Δ/a ratio will be larger for the autotype transformer.

3. The physical size of the transformer is controlled largely by the considerations discussed in part 2. For example, choice of the minimum mechanically or electrically feasible wire size will lead to the smallest possible transformer. However, it should be noted that even for a given wire size there is freedom of choice in the physical proportions of the transformer through the relations of equation 9. For example, a design may be realized for several different values of primary turns N_p, resulting in a choice among several of a given line of cores.

It should be noted that the physical size of the transformer is also related to the pulse duration, δ, through the rise time, t_0. If t_0 is to be a fixed percentage of the pulse duration, reduction of pulse duration requires a corresponding reduction in t_0. Reference to equations 6 and 7 shows that the transformer parameters, L and C, will change in proportion to the change in t_0. A study of equations 9 and 10 shows that as L and C are reduced in magnitude, the physical dimensions of the transformer also must decrease.

4. The primary winding for step-up transformers will be wound with two or more strands in parallel to give a closely spaced winding. This is necessary in order to satisfy the approximations under which the basic formulas for leakage inductance and interwinding capacitance were derived. Because of this requirement, two difficulties arise in practical design.

First, nonuniform distribution of current in the parallel strands, particularly for ratios of Δ/a less than about two,

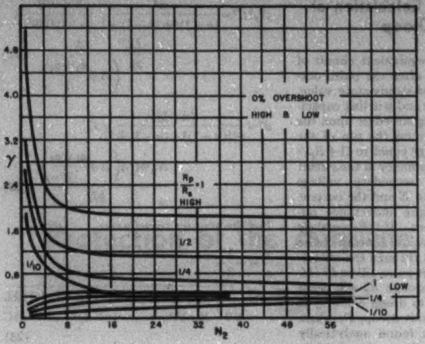

Figure 11. Impedance ratio, γ, versus N_2 for zero per cent overshoot, high and low, step-down transformer

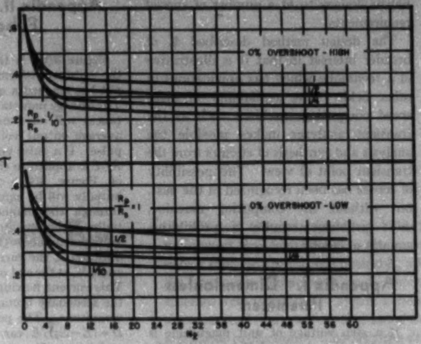

Figure 12. Per unit rise time, τ, versus N_2 for zero per cent overshoot, high and low, step-down transformers

cause the actual leakage inductance to depart from the required design value. This difficulty has been taken care of in the design procedure by introduction of the empirical factor, b, in the inductance formula. This empirical factor will range from one to two in magnitude and must be found by a series of approximating designs.

Secondly, for nonintegral ratios of transformation, it is difficult to obtain closely wound primary and secondary windings of practically equal length with equal primary and secondary wire sizes. With small wire size and low turns ratio, the difference in winding lengths may not be significant, and any small variation in parameters may be corrected by a proper choice of the factor, b. However, for other situations, it may be necessary to use unequal primary and secondary wire sizes. The extension of equations 11 and 12 to cover this situation is required.

Equivalent Circuit for the Step-Down Transformer

The complete primary-basis equivalent circuit of the step-down transformer is the same as that shown in Figure 3(A). All circuit elements shown will have the same interpretation as for the step-up transformer, except the turns ratio, n, will be numerically less than one. For the step-down transformer, the total secondary shunt capacitance, C_3, contains a term which is negative for turns ratios less than one. In many cases, the winding-to-core and external shunt capacitances, n^2C_{sw} and C_s respectively, are such that C_3 is negligibly small and may be assumed to be zero. Considerable data, too extensive to present in this paper, have been taken where C_3 is not small. It has been found that a design procedure based on the assumption, $C_3=0$, leads to satisfactory designs in all but extreme cases.

Therefore, under the assumption $C_3=0$, the dimensionless ratios and base unit time for the step-down transformer are found to be as follows:

Base unit of time, $T=2\pi\sqrt{LC_3}$

R_p/R_s

R_p/Z_0 (where $Z_0=\sqrt{L/C_3}$)

$C_3/C_1=N_2$

Design of the Step-Down Transformer

The design procedure for the step-down transformer is similar to that used for the step-up transformer. The basic pulse-front data giving per unit rise time, τ, and impedance ratio, γ, for zero per cent overshoot, both high and low, are shown in Figures 11 and 12. In these illustrations, the abscissa is the capacitance ratio, $C_3/C_1=N_2$, and curves are given for different values of R_p/R_s. For the step-down transformer, $\tau=l_0/2\pi\sqrt{LC_3}$ and $\gamma=R_p/\sqrt{L/C_3}$.

From the foregoing definitions, the required leakage inductance and effective interwinding capacitance of the transformer may be found.

$$L=\frac{l_0R_p}{2\pi\tau\gamma} \tag{15}$$

$$C=\frac{1}{1-n}\left(\frac{\gamma l_0}{2\pi\tau R_p}-C_{op}\right) \tag{16}$$

where $C_{op}=C_p+C_{wp}$. The relation between the capacitance ratio, N_2, and basic design specifications is found to be

$$\frac{l_0}{R_pC_{op}}=\left[\frac{2\pi\tau}{\gamma}\right]_{N_2}\frac{nN_2}{nN_2-(1-n)} \tag{17}$$

Equation 17 is analogous to equation 8 and is used in the determination of L and C from Equations 15 and 16, exactly as described in the case of the step-up transformer.

Equations 9 and 10 may be used without modification for the design of iso-type step-down transformers. Equations 11 and 12 will be changed because the primary winding is now the high-voltage winding and the coil length, d, for a single-strand close-wound primary is aN_p. Equation 18 gives the ratio, Δ/a, for the iso-type step-down transformer. The corresponding equation for the auto-type step-down transformer will be found in Appendix III.

$$\frac{\Delta}{a}=-\frac{1}{3}+\sqrt{\frac{1}{9}+\frac{0.0885}{12\pi10^3}\frac{k}{b}\frac{L}{C}} \tag{18}$$

Equations 13 and 14 are to be used in checking the top-of-the-pulse characteristics of the design. An oscillogram of a typical step-down design is shown in Figure 10(B).

Conclusions

A technique for designing pulse transformers has been described. This design method takes into account the transformer terminating impedances and permits control of certain specified features of the output wave form. The procedure is straightforward leading to an optimum design for a suitable set of transformer specifications. The design relations indicate clearly the possibility of realizing a design for a given set of specifications and, in many cases, provide several alternative designs to fit a number of special requirements.

The design method described is of broader interest in that it is illustrative of a technique which has applications in other fields. The availability of high-speed computing machines such as the transient analyzer makes possible the analysis and synthesis of circuits from the transient point of view. This possibility of course has been recognized in the past, but without the computing machine, most problems require a prohibitive amount of labor.

Appendix I. Dimensionless Parameters

If a step voltage of unit magnitude is applied to the circuit of Figure 3(B), the operational form of the load voltage, e_0, will be

$$e_0(p)=\frac{R_s(1+p^2LC_1)}{(R_p+R_s)+(L+R_pR_sC_2)p+[R_s(C_1+C_2)+R_pC_1L]p^2+R_pR_sLC_1C_2p^3}$$

Now, instead of using seconds as a unit of time, a new dimensionless time unit will be introduced, $t_1=t/2\pi\sqrt{LC_2}$. In other words, one per unit time is equivalent to $2\pi\sqrt{LC_2}$ seconds. When this change is made in the independent variable, e_0 can be expressed as an operational function of λ where $\lambda=d/dt_1=2\pi\sqrt{LC_2}p$.
The above substitution gives

$$e_0(\lambda)=\frac{2\pi\left(4\pi^2+\frac{C_1}{C_2}\lambda^2\right)}{8\pi^3\left(1+\frac{R_p}{R_s}\right)+4\pi^2\frac{R_p}{Z_0}\times\left[1+\frac{R_p}{R_s}\left(\frac{Z_0}{R_p}\right)^2\right]\lambda+2\pi\left[1+\left(1+\frac{R_p}{R_s}\right)\frac{C_1}{C_2}\right]\lambda^2+\frac{R_pC_1}{Z_0C_2}\lambda^3}$$

where $Z_0=\sqrt{L/C_2}$

From this equation, it can be seen that the time form of the solution for e_0 will depend not upon the magnitudes of the parameters, R_p, R_s, L, C_2, C_1, but upon the dimensionless ratios R_p/R_s, R_p/Z_0, and C_1/C_2. This permits the scaling of a particular problem to fit the frequency and impedance range of the transient analyzer and also permits a more concise presentation of data than would be possible using the actual circuit constants.

Appendix II. Calculation of Pulse Droop

Figure 3(C) is the equivalent circuit of the pulse transformer after the pulse output has reached a quasi-steady-state value. The leakage inductance and winding capacitances will have negligible effect upon the average output voltage on the top of the pulse. If a pulse voltage equal to $(1+R_p/R_s)E$ is applied to the primary of the circuit of Figure 3(C), the secondary voltage initially will be equal to E and the current through the magnetizing inductance initially will be equal to zero. If the secondary voltage remains at the value, E, for the pulse duration, δ, the current through the inductance, M, at the end of the pulse will be $E\delta/M$. This current flowing through R_p will cause the secondary voltage to droop below E in magnitude. The per unit droop, D, where $D=(E-E_\delta)/E$ can be found analytically as follows. If a step voltage of magnitude $(1+R_p/R_s)E$ is applied to the circuit of Figure 3(C), the actual instantaneous secondary voltage as a function of time will be

$$e=E\epsilon^{\frac{-R_pR_s}{M(R_p+R_s)}t}$$

For the usual transformer application δ is much smaller than $M(R_p+R_s)/R_pR_s$ so that at the end of the pulse duration, the secondary voltage will be approximately,

$$E_\delta=E\left[1-\frac{\delta R_pR_s}{M(R_p+R_s)}\right]$$

and

$$D=\frac{\delta R_pR_s}{M(R_p+R_s)}=\frac{\delta R_p}{M(1+R_p/R_s)}$$

Appendix III. Design Equations for Auto-Type Transformers

In the auto-type of pulse transformer, a portion of the secondary turns are closely coupled to the primary turns, either by winding side by side or by having two layers of winding separated by only a few mils of insulation. The closely coupled primary and secondary turns are usually made equal. With this arrangement, the following design equations result:

$$L=\left(\frac{n-1}{n}\right)^2b\frac{4\pi N_p^2U}{d}\left(\Delta+\frac{a_1+a_2}{3}\right)10^{-9} \quad (19)$$

$$C=\frac{(n-1)^2+(n-1)+1}{(n-1)^2}\;\frac{0.0885kUd}{3\Delta}10^{-12} \quad (20)$$

$$N_p^2U^2=\frac{n^2}{(n-1)^2+(n-1)+1}\;\frac{3\times10^{21}}{4\pi\times0.0885}\times\frac{LC}{bk}\;\frac{\Delta}{\left(\Delta+\frac{a_1+a_2}{3}\right)} \quad (21)$$

$$d^2=\frac{(n-1)^4}{n^2[(n-1)^2+(n-1)+1]}\times\frac{N_p^2bC\Delta\left(\Delta+\frac{a_1+a_2}{3}\right)}{kL} \quad (22)$$

For the step-up transformer

$$\frac{\Delta}{a}=-\frac{1}{3}+\sqrt{\frac{1}{9}+\frac{0.0885}{12\pi10^3}\;\frac{n^2[(n-1)^2+(n-1)+1]}{(n-1)^2}\;\frac{kL}{bC}} \quad (23)$$

For the step-down transformer

$$\frac{\Delta}{a}=-\frac{1}{3}+\sqrt{\frac{1}{9}+\frac{0.0885}{12\pi10^3}\;\frac{n^2[(n-1)^2+(n-1)+1]}{(n-1)^4}\;\frac{kL}{bC}} \quad (24)$$

Protection of the Airplane Main Bus

D. W. EXNER
MEMBER AIEE

INCREASED thought has been directed in recent years toward protection of the airplane electric system so as to improve its reliability and reduce the hazards which result from its failure. Up to and including the early years of World War II, little attention was paid to electric system protection beyond the obvious necessities of reverse-current relaying on the generator circuits and the use of fuses and small circuit breakers on the distribution circuits. During these years the size of the system was growing rapidly and the primary system voltage was advanced from 14 to 28 volts direct current. From the 1,500-watt 14-volt system on a popular pre-war commercial transport, system capacities advanced to 11.2 kw at 28 volts on the early *B-17* bombers and eventually to 50 kw on the *B-29*'s. Because there is little sign of slowing up in the trend toward greater installed capacities, particularly on military airplanes, higher voltage a-c and d-c systems have been in the process of development for the past ten years. Until very recently the greater emphasis has been on the 160-kva 208-volt 3-phase 400-cycle system because of its selection by the Air Force for the *B-35* and *B-36* bombers, and still larger versions of this system are in the offing. After a slow start some years ago, the 115-volt d-c system is finally undergoing a new intensive development for certain military applications.

In view of this growth in size and because greater dependence is placed on electric power on modern airplanes, certain phases of system protection are receiving much attention at the present time.[1,2] This paper will discuss methods for protecting the main bus. To set the stage, a brief history of airplane circuit protection is reviewed first.

Review of Protection History

As the electric systems became larger and operating conditions more severe, the circuit protection deficiencies were demonstrated by a number of cases of fires resulting from ground faults on the generator feeders and main bus. In some cases the generator contactor failed because of insufficient arc rupturing capacity at high altitude or because of contacts welding. Even if the contactor operated correctly, there was no provision for deenergizing the field in the case of a faulted generator or generator feeder. Out of these difficulties better designs of reverse-current contactors appeared,[3] but the need for some form of back-up protection was apparent. Fusible fault limiters designed to blow above normal overload levels proved to be a solution of sorts. Another solution was the use of manually-reset reverse-current circuit breakers located between the bus and the generator contactors and having auxiliary contacts to open the generator field circuit when the circuit breaker tripped. Initial experience with these circuit breakers was unfortunate, to say the least, because their lack of time delay allowed them to trip on normal system reverse-current surges and the necessity of locating them at the nacelles, adjacent to the generator contactors, made them inaccessible for manual resetting. Subsequent provision of some inverse time delay to these circuit breakers minimized the danger of nuisance tripping, and the modern tendency toward the use of a centralized bus in the fuselage permits access for resetting.

In the early stages of development of the 208-volt 400-cycle system in 1943, it was agreed that comprehensive alternator circuit fault protection was desirable, and the necessary equipment and control schemes were developed. Figure 1 shows a representative single-line diagram of the alternator protection. This provides differential current protection against alternator line-to-line and line-to-ground faults and includes the feature of opening the field circuit in case of fault. Alternator feeder faults are cleared by the use of multiple conductors with fusible fault limiters of an improved type[4] in each end of each wire. A form of back-up protection is provided by a thermal delay relay which removes the alternator from the line and opens its field circuit when the alternator excitation is maintained at ceiling level for longer than about six seconds.[5] As this is a nonselective type of protection, it is not intended that it should act except for such severe conditions as a major main bus fault or a bogged-down system caused by heavy motor starting loads when the generating capacity has been abnormally reduced by heavy combat damage.

Within the last two years good progress has been made in the development of integrated generator control and protection equipment for the 28- and 115-volt d-c systems. Up to the present time, the details which constitute the electric system usually have been designed and procured to individual detail specifications which ostensibly cover every requirement and condition of service, including the interaction with other pieces of equipment. With the inevitable different sources of supply, and the practical impossibility of writing a "hole-proof" specification, the result has been that our systems were nonhomogeneous in performance and deficient in protection. Now for the first time the d-c generation system has been studied as a whole by individual equipment manufacturers from the viewpoint of established industrial power practices, with the result that a much higher order of protection is offered with a relatively small increase in over-all weight and with greatly improved facility of maintenance.[1,2] In addition to genera-

tor and generator feeder fault protection, over-voltage protection is provided.

Since the earliest days of airplane electric systems, distribution circuits have had fuse or circuit breaker protection designed in general to protect the wire against dangerous overload. In many cases this has not been completely successful in preventing damage to the wire but generally has been able to interrupt in time to prevent fires. Particularly in commercial airplanes, but also in military airplanes, because of the adverse psychological effects, it is very desirable to avoid reaching wire temperatures at which the insulation gives off smoke or noisome odors. Distribution circuit breaker design has not fully kept pace with the increased fault current capacity of modern systems. Even the wartime *B-29* system, with armament amplidyne motor-generators in operation, was able to develop a peak fault current in excess of 12,000 amperes for a fault close to the main bus. The inadequate ultimate rupturing rating of small circuit breakers has in some cases required that back-up protection be provided by fusible limiters where it is necessary to tap loads from or near the main bus. Present practice in the 208-volt 400-cycle systems is to use three or more multiple circuits with fault limiter protection at each end of each wire so that a wire which develops a fault will be removed without losing the entire circuit. While this method is effective, the maintenance involved in periodic inspection of the many limiters required is excessive. This same protection may, perhaps be used on the 115-volt d-c system but will require careful study because of the limited sustained fault current capacity of the self-excited system operating without a battery and at a wide range of generator speed. Other methods of load feeder protection have been suggested, using current-balance or combined reverse-current and over-current principles, but to date none of these have been developed to the degree necessary for their use on airplanes. It should be mentioned that any method requiring the use of one or more pilot wires is not looked on with favor because of the added weight and increased vulnerability, particularly under combat conditions. While this feature may be tolerated within reason in generator protection schemes the much greater number of distribution feeder circuits makes it impractical.

The preceding review of the protection situation in airplane electric generation and distribution systems indicates that suitable methods are fairly well in hand with two exceptions:

1. Further work is needed on simpler and more effective methods of load feeder protection.
2. Main bus protection methods have not been developed to a satisfactory stage.

This paper concerns primarily a discussion of main bus protection.

The Need for Main Bus Protection

Practically all of the American multiengine airplanes flying today have an electric system in which two to six d-c generators or alternators are normally paralleled on a main bus from which the various distribution circuits extend, usually in a simple radial configuration.[6] The question of parallel versus isolated operation has been discussed many times in recent years, but it is generally conceded that motor starting and, in some cases, fault clearing requirements are met with minimum total generating capacity in a paralleled system.[7,8] Modern large airplanes have relatively large total motor loads, with a few individual motors approaching in some cases the rating of each generator. On the d-c systems some of the larger motors and a rather high percentage of the total motor load will be shunt or compound wound, so that the motor contribution to peak fault current will be high.[9]

The main bus in the paralleled system constitutes a principal vulnerable point, damage to which can disable the entire electric system. Recognition of this fact influences the designer to devote special attention to design and location of the bus structure so as to reduce the possibility of damage. For commercial airplanes at the present time, this is the best solution and is preferable to the added complication and weight of protective relaying. For combat airplanes such design treatment is, of course, necessary also, but some suitable form of quick-acting automatic protection is needed badly.[10] No amount of care in design, installation, or even armoring can eliminate the chance of missile damage completely. A direct hit on a bus compartment, or a nearby explosion, is almost certain to produce an electric fault either by impact damage to the conductors or by tearing and curling adjacent structure into contact with the bus. Methods for minimizing the results of such damage will be discussed.

Protection by Reducing Exposure

The first principle of bus protection is, naturally, to decrease the exposure area. Most multiengine airplane designs up to and including the war years used a wing-to-wing main d-c bus, shown in Figure 2. This showed weight economy by permitting engine starter and accessory loads to be tapped off in the nacelles instead of running separate feeders back from the center section. Although some postwar designs still use this method, it cannot be considered good practice from the safety standpoint. In such cases, the bus occupies the same general area with hydraulic lines and mechanical control cables and is adjacent to fuel tanks and lines. It is in a hot area when thermal wing de-icing is used. Extra precautions must be taken against abrasion failures of insulation and possible cable damage during maintenance work on other facilities in that area. Under combat conditions, it is extremely vulnerable to missile damage. If the bus itself is concentrated in the center section, the generator feeders which have to run through the wing section can be protected fairly well by present current-balance methods.

Location of the main bus in the fuselage offers maximum reduction in exposure area and incidentally improves the voltage regulation. The effective size of the bus is then determined mainly by the number and size of the generator contactors and load feeders which must be attached to it. It may be beneficial to move many of the secondary load circuits to separate load busses which are fed from the main bus through multiple conductors individually protected at each end by fusible fault limiters. The area around, and particularly above, the main and load busses should be kept clear of fuel, hydraulic, alcohol, and oxygen lines. In a recent case which emphasizes this point, a mechanic was tightening a connection to a circuit breaker at a load point. His screwdriver slipped and made contact with an oxygen line, starting a fire which caused heavy damage to the airplane before it was extinguished.

Much can be done to reduce the vulnerability of a bus by careful attention to arrangement and insulation so that foreign objects such as loose washers or small tools cannot create a fault. During the war, a new *B-29* was lost in Puget Sound because of conditions initiated by a fault which resulted from a loose washer lodging between two terminals of a reverse-current contactor. In this case, the design of the contactor was at fault, offering an example of the need for adequate enclosure and for insulating terminal guards on electric equipment.

Insulated Bus Compartments

At the present time, the use of bus compartments constructed entirely of insulating material is being considered seriously. Present techniques in the use of glass fiber laminates make this attractive and apparently practical. Needless to say, the resin should have nontracking and fire-resistant properties. Attention should be given to the location and shielding of any metallic attachment fittings so as to prevent accidental contact between the bus and those details which are at ground potential. A minor weak point in this arrangement is the need for control circuit ground connections to the coils of the generator contactors located inside the bus compartment. It would seem desirable from a safety standpoint to leave the contactor frames ungrounded and to complete the control ground circuits through number 20 gauge wire leads which can burn clear in the event of an internal breakdown in the contactor.

The construction of an equally safe 3-phase bus compartment presents more difficulty because of the dual danger of phase-to-phase and phase-to-ground faults and because of the unavoidable crossovers resulting from connections to the bus. The use of solid noncombustible insulating barriers between phases and at crossovers is good practice. The crossover problem becomes simpler if the three phases are stacked or staggered in depth.

Mechanical Protection

For protection against missile damage some use has been made of armor plating the bus compartments, although the constant struggle with weight problems on airplanes makes this extremely unattractive if it is made reasonably effective. In some cases it has been possible to obtain a certain degree of flack protection by suitable location with respect to heavy primary structure such as wing spar caps. There is then the probability that a direct explosive hit which would destroy the bus will do enough structural damage that the bus failure will be incidental.

The Sectionalized Bus

If we assume that a means is available for isolating a faulted bus section, it goes without saying that the bus must be arranged in two or more sections in order to obtain any benefit in continuity of service. In a commercial airplane the sections may be all in one compartment with suitable barriers. In a combat airplane, however, it is important to have the sections in separate compartments, well separated to minimize the chance of simultaneous damage. So as to avoid excessive exposure, the bus tie conductors should be run in spaced multiple with fusible limiter protection at each end of each conductor. Additional security is obtained if the bus sections are connected in a ring configuration so that the isolation of a central section will not cause the loss of parallel operation. The ring arrangement makes better use of the remaining generating capacity to blow the limiters to a faulted section and may also justify the use of lighter individual bus tie lines and tie limiters, the latter making easier the matter of clearing a faulted section. Vital loads on an airplane usually are duplicated, in which case they may be distributed over two or more bus sections.

Sectionalizing Through Fusible Limiters

For automatic isolation of a faulted bus section the fusible limiters in the tie lines function reasonably well under generating and load conditions which result in high fault current. This means having all or nearly all generators in operation, well loaded, and preferably with shunt motors on the line to contribute fault current. In the case of a d-c system a more favorable condition is to have the generators operating at speeds somewhat

Figure 2. Typical 28-volt wing-to-wing bus

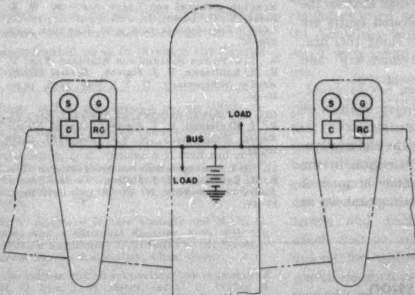

Figure 3. D-c bus section protected by ground-current tripping, with reverse-current and current-balance protection on generator feeder

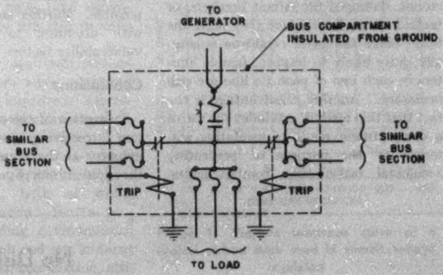

above the minimum. As the system load is reduced or generators are lost from service the short circuit current capacity goes down and limiter blowing time lengthens until eventually it may become excessive. Because of the wide range of possible operating speed, which is a desirable feature of d-c systems, exciters have not been practical and therefore such systems are at present universally self-excited. This limits their sustained fault current capacity. In the 400-cycle system the alternators have individual exciters and, under a solid fault to the main bus, can deliver an ultimate sustained fault current which is appreciably higher than the transient current. On systems having a high percentage of motor loads, nevertheless, one cannot depend on the ultimate fault current for blowing limiters without running into the danger of essentially stalling all motors because of the long time involved. This may leave the system with a heavier starting load than it can pick up, and it may remain stalled until manual supervision removes the major motor loads. Calculations backed up by some tests on the 400-cycle system indicate that a clearing time longer than about 0.1 second may lead to this condition.

Ground-Current Relaying

Because of the imperfect performance of limiters for main bus protection, other faster and more selective means are needed for combat airplane systems. An inherently instantaneous method which has been proposed[11] is shown in Figure 3. Here the metallic bus compartment is insulated from the airplane structure except for a path through the low-impedance trip coils of the circuit breakers. The trip coils must be designed to operate even though they are partially short circuited by a low-impedance fault between box and ground. It is also to be assumed that battle damage to the box has not ruptured the trip coil circuit, damaged the circuit breakers, or faulted the tie lines where they leave the box. Since the latter condition is actually quite likely to happen, fusible limiters in each end of each tie line are still necessary. Another disadvantage is the fact that this method precludes the use of a compartment made of insulating material for the purpose of preventing accidental rather than combat faults, unless a heavier composite construction is used. Because of the difficulty of sensing phase-to-phase faults, and the problems in designing a 400-cycle trip magnet, it would seem that this method is best suited for d-c systems. As far as the author is aware, circuit breakers for this protection method are not yet available for airplane use.

Differential-Current Protection

Although differential-current bus fault protection is used widely in industrial practice, its use on airplane 400-cycle systems, especially under combat conditions, does not appear at all attractive. The difficulty arises principally from the large number of points at which current must be summed, particularly when line-to-line as well as line-to-ground faults are to be detected. Although 400-cycle current transformers are individually small and relatively light, the large number which is required enlarges the bus compartment so much that vulnerability is greatly increased. A broken control wire or a grazing hit on one transformer is sufficient to trip the bus off the line although the bus itself may be undamaged. While use of this method only for ground fault protection will reduce the number of transformers by two-thirds, when using through-type transformers, the lower order of protection obtained offsets the slight improvement in vulnerability. Also the reduction in number of transformers is obtained at the expense of bunching all conductors of all phases at the transformer, and this is a questionable practice. The need for bus-tie circuit breakers in either of the foregoing methods adds to the bus compartment size and vulnerability.

For the d-c systems it is conceivable that an arrangement of directional over-current relays might be devised to detect a bus fault and clear it by means of bus-tie circuit breakers. In some respects the problem appears simpler than that for the a-c case because only ground faults are possible. Further study along this line, with attention to nuisance-trip and vulnerability factors, is suggested.

Conclusions

Protection of the airplane electric system is receiving much attention in the industry at the present time because of the rapid growth of generating capacity in recent years and the greater dependence of airplane safety and performance upon the system reliability. While methods of generator circuit protection are fairly well in hand, the main bus, and to a lesser extent the distribution circuits, are inadequately protected because fully effective methods are not yet available. Although improved bus structure design and installation, such as the use of nonmetallic bus compartments, may afford sufficient protection for noncombat airplanes, more-positive and faster-acting protection is urgently needed in combat systems. At the present time the safest bus is the ring type with dispersed bus sections interconnected by multiple-conductor limiter-protected bus tie lines. The clearing time for a bus fault in this system is dangerously long after partial loss of generating capacity and may result in system collapse because of stalled motor loads. Further work on simple low-vulnerability bus protection methods is needed and there is a possibility that some form of directional over-current relaying would be suitable.

Aircraft Carbon-Pile Voltage Regulators, Fundamentals, and Design Improvements

B. O. AUSTIN
MEMBER AIEE

H. H. C. RICHARDS
NONMEMBER AIEE

IT HAS been known for many years that mixes of carbon can be processed into plates of various shapes, hardnesses, finishes, and thicknesses. When these plates are stacked and pressure applied at right angles to their surfaces, the resistance of the stack varies with the pressure change. Figure 1 is a typical curve of pressure plotted against resistance for such a carbon stack. This curve shows that the resistance decreases with an increase of pressure. The design of the carbon-pile voltage regulator is based on this fundamental characteristic of carbon surfaces in series under a controlled variable pressure.

D-c generator field strength is one of the determining factors for output voltage. Field strength may be controlled by varying the current with variable series resistance. Stacked carbon plates provide such a resistor when the applied pressure is properly controlled. Many designers in the past several decades have conceived a large variety of electromechanical mechanisms for controlling the pressure on carbon piles. These mechanisms have consisted usually of levers, cams, pivots, dash-pots, springs, rollers, magnets, and electrical dampers co-ordinated so as to produce the desired results.

Generally, the main design objective for carbon-pile voltage regulators is to provide an electromagnet with the necessary mechanisms arranged so that the pull curve of the magnet matches the force curve of the spring throughout the operating travel range of the magnet armature to properly control the pressure on the carbon stack. See Figure 2 for a typical matching curve. This accomplished, the device becomes a servomechanism for automatically regulating the resistance in series with the field winding of the generator to hold constant voltage output when the regulator operating coil senses generator voltage.

Carbon-pile voltage regulators designed for aircraft use appeared in quantity on military aircraft early in World War II. These regulators were similar to the English design by Newton which were of the direct-acting type with many of the mechanical arrangements common to the carbon-pile voltage regulators eliminated. Due to their mechanical ruggedness and ability to withstand momentary overload, they have been more successful than other types of regulators used previously. Even with the difficulties which have been experienced with them, they are still in wide use.

Many of the users of aircraft carbon-pile voltage regulators have suggested that the regulators be improved. Operators want longer life, easier maintenance, better temperature compensation, no creeping, no fluttering, no over-voltage due to stack wear, and minimum hysteresis and friction, both of which affect voltage regulation. Better provisions for withstanding environmental conditions such as high and low ambient temperature, vibration, acceleration, altitude, sand, salt spray, and humidity are further refinements desired.

In further consideration of the improvements in the design of the aircraft carbon-pile voltage regulator, it was found that it is much easier to build satisfactory regulators in model shops than to produce satisfactory regulators of the same design in the production line unless the design is adapted to easy accurate methods in obtaining close tolerances and perfect alignments of vital parts.

Performance Objectives

With the performance data from actual service at hand and with a wealth of information from production experience, it was clear that a complete study of all factors affecting the performance and production of aircraft carbon-pile voltage regulators was long overdue. The first requirement of any voltage regulator is accurate regulation. Regulator performance, as outlined in the *AN-R-la* Specification issued by the United States War and Navy Departments, is required from minimum generator speed to maximum generator speed with generator load varying suddenly or gradually over the load range. The load may be suddenly removed or applied at any time. This operating load condition may repeat at low or high ambient temperatures or under altitude conditions. Regulator

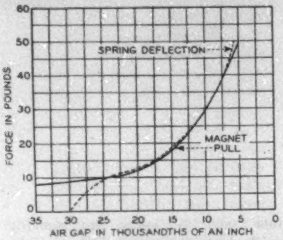

Figure 2. Curve showing matching between spring force and magnet force in the aircraft voltage regulator

performance must be such that minimum stack resistance will permit satisfactory generator output at low speeds. On the other hand, the maximum high resistance values at no-load and maximum speed must be accurate and stable under conditions of vibration. It is further required that the voltage controlled by the carbon-pile voltage regulator during load changes between rated load and no-load shall recover in the order of 0.1 second or less. Regulators are sometimes subjected to full field current through the stack and must carry this overload current for a long period without damage to any operating parts. Carbon-pile voltage regulators in operation on airplanes are subjected to periods of continuous acceleration. This is a severe operating condition which must be met without loss of regulation at high generator speed and high stack resistance, and the regulator must remain stable. Paralleling equalizer coils must be provided in the regulator so that satisfactory load division will be maintained by the generators. See Figure 3 for the diagram of paralleled regulators and generators.

Total temperature produced by watts loss in a carbon-pile voltage regulator determines the watts rating at which the regulator can be operated without unusual wear or damage affecting voltage regulation. Therefore, the design must be such that the regulator will dissipate the rated watts without overheating any of its parts. Endurance is closely allied with temperature, stability, time of recovery, pressure range on the stack, and the magnet air gap. Therefore, it is required that these factors (as well as the dielectric strength of insulating materials which are also affected by temperature) be properly considered in the design. The regulator also must have the ability to withstand sand, dust, salt air or spray, high or low humidity, and resistance to fungus growth.

Design Procedure and Results

There are many factors governing the carbon stack design which must be considered and accounted for if long life and good performance are to be expected. The operating temperature of carbon is limited by disintegration at the surface of the plates and therefore watts loss of these surfaces must be within the temperature limits of the carbon surfaces, which is in the order of 400 degrees centigrade. Resistance per inch of length of the carbon plates or disks must be controlled so as to limit the watts input. Therefore, the total length of the stack is determined largely by how fast the carbons can be cooled and the maximum temperatures that carbon can stand without disintegration. It is not advisable to blow air directly on the carbon stack as the oxygen present accelerates combustion at the hot spots.

Carbon plates in stacks do not make contact uniformly throughout the area of the plates. This is due to very minute high spots, even with the best grinding and polishing methods. Heat is concentrated at the points where high spots first make contact. This may result in glowing or overheating of the carbon at the localized points if the volts and amperes per plate are too high. This is controlled by providing the proper number of plates per inch of stack length. Therefore the permissible watts for each contact surface are a determining factor in the number of disks per inch. There seems to be no known means of cooling these hot spots fast enough to prevent disintegration of the carbon and to permit a reduction in the number of carbon plates and the lengths of stack in a given application.

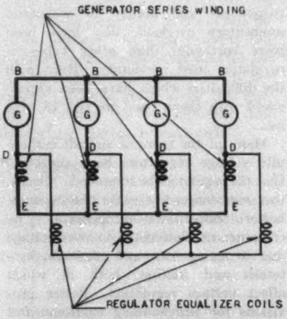

Figure 3. Diagram of equalizer circuits for equalizing generator loads

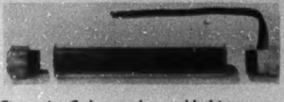

Figure 4. Carbon stack assembled in a pyrex tube and the electrodes for the aircraft carbon-pile voltage regulator described

Two other important factors entering into the stack design are the minimum and maximum resistance to be obtained under operating conditions and the available forces in the magnet and spring. A large number of disks per inch aid in obtaining maximum resistance, reduce arcing between plates and provide stability. On the other hand, a small number of disks aid in obtaining the minimum resistance. The design must be compromised between these two factors and the hardness of the carbon.

Stack sizes or diameters should be kept small provided they can be cooled satisfactorily. This is to minimize the weight of the stack which aids in the solution of vibration and manufacturing problems. The smaller diameter disks are easier to grind flat and they remain flat after heating in the regulator. Large rigid disks are hard to grind and warp easily with temperature. This can seriously affect the performance of the regulator. Very thin disks may be acceptable when they can be produced with sufficient strength. In this case, the surfaces of the carbon disk would adjust themselves to one another by bending. Figure 4 shows the stack used in the improved regulator.

The method of cooling and the necessity for enclosing the carbon stack make it necessary to support the stack with a tube made of such material as Pyrex glass or ceramic. Both of these materials are satisfactory; the ceramic material being a little more difficult to grind and polish to eliminate friction.

Probably the most important structure in the carbon-pile voltage regulator is the armature and its associated parts. The vital parts of this armature consist of an iron disk, an abutment on which the spring rests, a damper, a spring, a spring clamp, insulation, electrode, and hardware.

For the purpose of obtaining quick response and eliminating difficulties due to vibration, the component parts of the armature assembly which move are kept as light as possible. A flat star-shaped spring is used whose ends rest on an outer abutment ring. The ring surface is shaped so that as the spring travels, the forces required to make it travel are nonlinear and match the pull curve of the magnet. For maintaining accuracy of the assembly, this special design uses a star-shaped spring which is flat and is not formed before being included in the armature assembly. During the assembly of the armature an inner and an outer cone-shaped coined washer clamps the spring and forms it to the desired angle. This eliminates the manufacturing difficulties of accurately forming springs. In this same assembly there is a thin, soft, copper diaphragm whose purpose is to air and spring damp the action of the star-shaped spring and control the wear curve of the regulator, minimizing armature flutter and over-voltage due to carbon stack wear.

The problem of excessive heat transfer from the electrode and carbon stack to the star-shaped spring was solved in the regulator shown by using a ceramic bushing support for the electrode which is clamped into the armature assembly. The ceramic was selected for its high heat insulating characteristics. The electrode has a shunt which is attached to the electrode by tamping. The shunt passes through a slot in the side of the ceramic bushing. The electrode can be removed from the ceramic bushing in about the same manner a carbon brush is removed from a generator. This provides an armature which is very stable and is not subject to change or shrinkage such as that experienced with other types of armatures. See Figure 5 illustrating the component parts of the armature assembly.

Magnetic forces to operate the armature are rather simple and are subject to standard calculations. The pull curve is matched to the armature spring as nearly as it is practical to do with such a design. Structural studies of the magnetic circuit were made and the circuit arranged so as to provide the maximum ease in the accuracy of assembly during production and maintenance operations. Hysteresis in the magnetic field is minimized by thoroughly hydrogen annealing all iron in the magnetic circuit. In addition a high grade iron is used to eliminate as many impurities as possible.

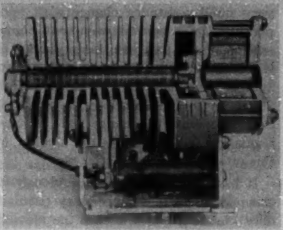

Figure 6. Cut-away view of the aircraft carbon-pile voltage regulator

The stationary electrode is the same as the moving electrode except that it does not have a shunt and is pressed into a metal threaded plug. It is removable and replaceable. Removing the stationary electrode plug permits the removal of the carbon stack without further disassembly. This plug is clamped in place by the support casting being split and closed with a clamp screw.

Heat dissipation and thermal expansion are controlled by the amount of radiating surface and the characteristics of the materials used. The carbon stack which is to be cooled is enclosed in a Pyrex tube which is not a good heat conductor, but is acceptable from this standpoint and is used. This material and a ceramic are about the only ones that will stand the heat shocks and provide the necessary insulation. The stack diameter, the inside and the outside diameter of the Pyrex glass tube are controlled as closely as it is practical to avoid blankets of air which also are very poor conductors of heat. Tolerances between the glass tube and the metal tube of the housing are closely controlled for the same reason.

Heat is finally dissipated by means of cast aluminum fins on an invar steel tube. The number and area of these fins depend on the watts to be dissipated and the maximum allowable total temperature rise of the carbons. An aluminum cast housing for cooling and supporting the structure has been a problem due to the high temperature coefficient of the expansion of aluminum. The problem was solved by casting the aluminum fins separately on an invar tube which has a very low temperature coefficient of expansion. In this manner, the individual aluminum fins can expand, but do not affect the over-all expansion of the housing. Temperature rise of the invar tube is about 135 degrees centigrade for 90 watts dissipation. See Figure 6 for a cut-away view showing this construction.

Carbon stacks and electrodes have not as yet been designed so that they will have an indefinite life. They are an item of wear and must be replaced. The regulator structural design was studied thoroughly and arranged so that any of these parts could be removed and replaced within ten minutes. At the same time, the design also was arranged so that when it was disassembled or reassembled there would be no errors of misalignment which could cause poor voltage regulation due to increased friction of parts being pushed sidewise. See Figure 6.

External to the body of the regulator is a 1-piece mounting bracket or base on which are mounted three resistors and the necessary terminals. The variable re-

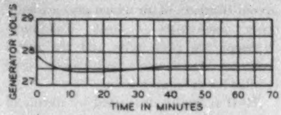

Figure 8. Voltage regulation curve during a 70-minute warmup period from a 25 degree centigrade ambient

sistor is in series with the operating coil of the regulator. The purpose of this is to set the regulator voltage within the established limits. It was felt by the designers that an improvement could be made by providing a locking nut for this adjustment, rather than by using a detent or ratchet mechanism to hold the adjustment in place. The locking nut can not be changed so easily by unauthorized persons and it has, therefore, been provided. The fixed resistor is in series with the operating coil and is for temperature compensation, which will be discussed later. The fixed stabilizing resistor is connected so as to form a feedback to the operating coil, thereby stabilizing the action of the coil in the magnet circuit of the regulator. See Figure 11.

Aircraft carbon-pile voltage regulators are subjected to a very high range of temperatures from ambient sources as well as warm-up due to heat generated within them. For this reason, temperature compensation of the regulator was thoroughly studied and means were provided for correction. Several variations of materials such as steel whose magnetic characteristics change with temperature were tested and evaluated. The design was finally co-ordinated with materials used in the construction of the regulator. With such an arrangement, the adding of details for temperature compensation was unnecessary. This arrangement involved the proper location of invar alloy and the aluminum support for the magnet assembly. (See Figure 6.) Also note that tie rods formerly used have been eliminated. A fixed resistor mounted on the base is connected in series with the winding of the operating coil. It has a very small resistance change with temperature and is used to swamp out a large portion of the total resistance change of the operating coil. The ratio of the resistance of the resistor to that of the coil is about 4.4 to 1. Therefore, the effect of coil temperature change on voltage regulation is reduced by the amount of this ratio.

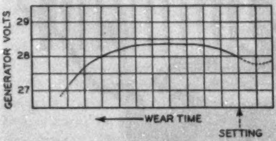

Figure 9. Curve showing voltage regulation due to stack wear. Wear time depends on regulator application

It has been pointed out previously in this paper that it was necessary to minimize the weight and anchor the moving parts of the armature. This was done and proved to be very helpful in the solution of the vibration and centrifugal force problems. The carbon stack also is a free member and is subject to this same service condition. Likewise, its weight, as well as the number of disks in the stack, is important. A small number of disks require less pressure and separate more readily under vibration. Therefore, the number of disks to be used is a compromise between arcing conditions at the disk surfaces and arcing due to vibration.

Endurance or life of an aircraft carbon-pile voltage regulator depends on many factors, some of which have been discussed previously in this paper. Carbon stacks must be operated at or below the recommended temperatures to prevent disintegration. Flutter or unstable action of the armature must be damped out or otherwise excessive arcing and burning will take place at the electrodes and between the disks. Effects of vibration, acceleration, and centrifugal forces on these moving parts must be minimized. Grade or hardness of carbon disks used must be carefully selected and co-ordinated with many other factors in the stack design. Operating stack pressures must be sufficient to prevent arcing under maximum resistance conditions.

There are several environmental conditions, with which many are familiar, under which aircraft carbon-pile voltage regulators must be operated satisfactorily. These are sand, dust, salt air, humidity, and fungus growth. After a thorough study, arrangements were made for the effective sealing of the vital parts against these hazards. Wherever possible, pressure is used at the open joints and high temperature soft synthetic seals are used at cable entrances. Considerable improvement has been made at the armature assembly enclosure where exclusion of sand, dust, and other foreign materials is highly important. Materials subject to fungus are treated with the best known preventatives. See Figure 6 for the assembly seals.

Test Results on 90-Watt 28-Volt Regulator

1. Voltage regulation at 3,500 rpm of a 200-ampere United States Air Force type *P-1* generator varied from 0 to 0.3 volt for three observations, zero load to full load.

2. Voltage regulation at 4,500 rpm of a 200-ampere type *P-1* generator varied from 0.2 to 0.3 volt for three observations, zero load to full load.

3. Voltage regulation at 3,500 rpm of a 200-ampere type *P-1* generator varied from 0.05 to 0.4 volt for three observations, zero load to full load at −55 degrees centigrade ambient.

4. Voltage regulation at 4,500 rpm of a 200-ampere type *P-1* generator varied from 0.1 to 0.4 volt for three observations of zero load to full load at −55 degrees centigrade ambient.

5. Voltage regulation at 3,500 rpm of a 200-ampere type *P-1* generator varied from 0.1 to 0.3 volt for three observations of zero load to full load at +72 degrees centigrade ambient.

6. Voltage regulation at 4,500 rpm of a 200-ampere type *P-1* generator varied from 0.2 to 0.3 volt for three observations of zero load to full load at 72 degrees centigrade ambient. (See Figure 8).

7. Dielectric strength was satisfactory at 500 volts for one minute from live parts to base.

8. With 0.25 volt applied to the equalizer coil, the regulator voltage was lowered 2.35 to 2.50 volts on ten regulators.

9. Minimum resistance varied from 1.17 to 1.22 ohms on the ten regulators tested as per Specification *AN-R-1a*. Resistance of 1.25 ohms or less is acceptable.

10. Maximum resistance of 35 ohms under vibration conditions without producing arcing in the stack is shown by curve in Figure 11.

11. Maximum recovery time tested 0.06

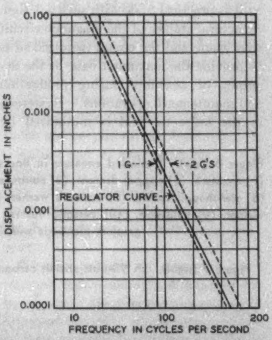

Figure 10. Regulator stack arcing elimination test between one and two gravitational units under vibration conditions. Taken on regulator described

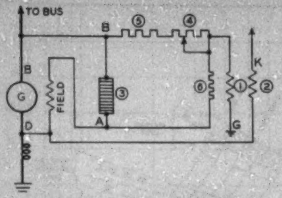

Figure 11. Schematic diagram of connections for the 90-watt aircraft voltage regulator

second. Recovery time of 0.10 second is acceptable.

12. Voltage regulation at 4,500 rpm of a 300-ampere *P-1* generator, 72 degrees centigrade ambient, after 25 hours varied from 0.1 to 0.3 for three observations zero to full load.

13. Carbon stack closed with no voltage on the operating coil. Regulator withstood 15 amperes through the carbon stack for one hour without damage.

14. Maximum increase in ripple, voltage tested to be 0.35 volts, while 0.6 volt is acceptable.

15. Regulator was placed in a centrifuge under the most unfavorable conditions (coil end toward center, stack radial); satisfactory operation was observed up to 6 G's (acceleration due to gravity). 5 G's acceptable to Specification *AN-R-1a*.

16. Regulator was vibrated for two hours in each of three directions making a total of six hours without shock mounts; 10 to 55 cycles at 0.06 total excursion. No damage resulted.

17. At the end of a 200-hour accelerated endurance test the voltage dropped 0.7. The voltage did not change more than 0.3 during any 25-hour period.

18. Regulator was subjected to salt spray for 25 hours, passing regulation requirements afterwards.

19. Regulator was subjected to sand resistance tests for eight hours. At the end of the test, voltage had changed 0.1.

Conclusions

Objectives accomplished in this program of designing and improved aircraft carbon-pile regulator resulted in the following:

1. Better voltage regulation.
2. Lower operating temperatures.
3. Improved acceleration and vibration characteristics which affect life and regulation.
4. Longer life.
5. Sealed protection against salt spray, sand, and other foreign objects.
6. Good temperature compensation without added details.
7. Friction and creep reduced very substantially.
8. Better performance under high and low ambient temperature conditions.
9. Wearing parts made readily accessible and replaceable.
10. Reduction in the number of parts.
11. Disassembly and reassembly without change in alignment.
12. Improved armature construction.
13. Dissipates a maximum of 90 watts.
14. Weight increased about two ounces over regulators of 75-watt rating.
15. Design well adapted to production and maintenance of alignment of parts.

Current Ratings of Aircraft Cable

WADE H. ASKEW
ASSOCIATE AIEE

A. T. McCLINTON
MEMBER AIEE

Synopsis: This paper presents the results of an investigation conducted to determine the continuous and short-time current ratings of copper aircraft cable, using visual indication of smoke as the limiting factor. Tests were made on several wire sizes at various ambient temperatures, using six types of aircraft cable. Curves were obtained showing the highest current which can be carried continuously by each size of cable at different ambient temperatures without evolvement of smoke. Thermal curves, with smoking and delayed smoking values, were obtained for various current overload applications. Procedure is given for interpolating smoking and delayed smoking curves for wire sizes not experimentally obtained. Results of this investigation indicate that present continuous current ratings are too high for most of the cable used during this investigation.

MUCH of the electric equipment in aircraft is used, or draws its greatest current, for short periods of time. When voltage drop is not a restricting item, considerable saving in weight and material can be realized by the use of small size cables to carry, for these short periods, currents much higher than the continuous ratings. If the wiring system is designed on the basis of cables being subjected to overload currents, it is necessary that protective devices be installed to make certain that the interval of application shall not exceed the safe time limit. Proper co-ordination between protective equipment and short-time ratings is necessary to assure that the cable will not be subjected to an excessive overload-time combination.

Tests conducted previously by other laboratories indicate that, for short-time periods, a conductor temperature sufficient to produce light smoke will cause no measurable change in the insulating or physical properties of the cable. However, any trace of such smoke in a plane is psychologically dangerous; therefore, the wiring must be protected from possible smoke evolvement.

Definitions

Certain terms used throughout this report are defined as follows:

Maximum Continuous Current. The highest current which can be carried for an unlimited time by a specified cable at given ambient conditions without producing visible evidence of smoke.

Overload. Any value greater than the maximum continuous current.

Smoking Time. The time required to produce visible evidence of smoke when an overload current is carried by a cable.

Delayed Smoking Time. The longest interval of time an overload current can be carried by a cable without visible evidence of smoke occurring after the current is interrupted.

Methods of Conducting the Investigation

Tests were conducted on single cables in still air, at approximately sea level altitude, in ambient temperatures of 0, 25, and 45 degrees centigrade. Cable sizes *AN* numbers 0, 8, 16, and 20 from various manufacturers were used for the investigation. Data for other ambient temperatures and cable sizes were interpolated from the results experimentally obtained.

The conductor temperature was ascertained at any time during test runs by calculating the change in resistance as indicated by the change in voltage drop across a section of the cable. A submarine battery was used as the source of power; the current was held constant by variable resistors, paralleled as necessary for the various currents used. Tests proved that when only light traces of smoke evolved, the same cable could be used several times without noticeable change in any of the measured results. When the sample was used more than once, subsequent tests were made only after the cable had cooled to room ambient temperature.

Since the appearance of smoke determined the length of time the cable could carry a specified current, it was necessary to have an accurate method of detecting the smoke. Preliminary test runs showed that the best results were obtained in a partially darkened room, using a small desk-type fluorescent lamp secured about three inches above the cable. A piece of photographer's cloth was hung about three feet behind the light, and a small strip of this cloth was suspended just below the light, about two inches in front of the cable. It was found that accumulation of smoke in the lamp shade was particularly helpful in observations where the time at which smoke appeared was not an essential factor, that is, observations for determining continuous current

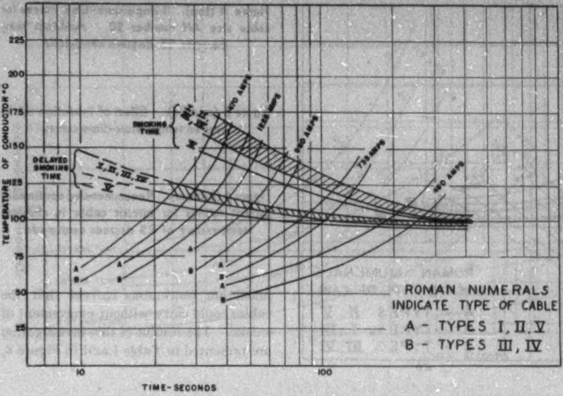

Figure 2. Temperature–time curves for cable size *AN* number 1/0. Ambient temperature 25 degrees centigrade

and delayed smoking values. The best position for observation was found to be 12 to 24 inches directly in front of the light.

Consideration was given to the possibility that different individuals might not detect smoke at the same time under similar conditions. However, data taken from observations made by six persons during a minimum of 20 test runs showed that except for the first five or six observations, the difference is observed time for the various individuals was well within the experimental error.

Figure 1 shows a schematic diagram of the test circuit. The by-pass circuit consisted of three parallel cables, each of the same size as the cable under investigation, but three times its length. This circuit was used for the initial setting of the variable resistors. Carbon piles were used for the variable resistors since their change in resistance partially compensated for the change in resistance of the cable, thus facilitating the maintenance of a constant current. Weights of 20 pounds for size number 0; 5 pounds for size number 8; and one pound for size number 16 and number 20 cable were hung over a pulley with a cord connecting the weight to the cable. Any slack caused by elongation due to temperature rise was taken up by the weight, and the tension was kept constant. These weights were not sufficient to cause stretching of the cable.

Discussion of Results

Figures 2, 3, and 4 show conductor temperature versus time curves for overloads applied to the various types and sizes of cable. The delayed smoking time values shown on these and other curves establish the overload-time values for the cables; but for comparative information, the smoking time values also are shown. It will be noticed that the grouping of thermal, smoking time, and delayed smoking time curves by types is not consistent for the different sizes of cable used during the investigation. This is probably due to different graduated scales used by the manufacturers to determine the relative amounts of primary insulation and braid components for the various sizes of cable. For example, it was found that the weight ratio of primary insulation and/or braid to the total weight of the cable might be nearly equal on one size for cable from four of the manufacturers, whereas when the same type of comparison was made using another size, this weight ratio would be about the same for possibly only two companies; and for a third size, these ratios would be different for all of the manufacturers.

Several tests were made to determine the effect of increase in insulation thickness (outside diameter), the results of which are shown in Figure 5. No attempt was made to determine the thickness of any material added or removed, but attention is directed to the fact that every material added decreased the operating temperature of the conductor, and that the type of outer surface apparently had little effect. Also, this indicates that the heat dissipated from the cable by conduction and convection is large compared to that dissipated by radiation.

In addition to the data mentioned previously on short-time temperature characteristics, data were obtained to show the

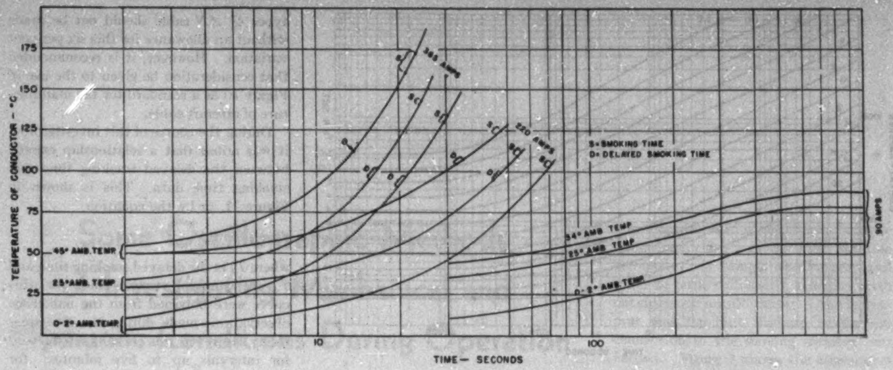
4	20	20	105.2
5	8	92.5–95.0	90.4–92.7
5	20	17	84.5

* Ambient temperature—25 degrees centigrade.

The values shown in Table I are the highest currents that the respective cables could sustain without causing the insulation to smoke while operating in an ambient temperature of 25 degrees centigrade. Those of Figure 6 are the average continuous current values for the six types of cable investigated. It should be noted that most of the conductor temperatures in Table I are lower than the 100 degrees centigrade generally accepted as being satisfactory.

The effect of ambient temperature on short-time and continuous ratings of the various cables also was investigated. Figure 7 shows the thermal curves with smoking time and delayed smoking time values obtained on one type of cable at various ambient temperatures. The average maximum continuous current ratings are shown in Figure 8. It should be noted that the current rating curves will all approach zero current at 95 degrees centigrade.

These tests were extended to show the effects of ambient temperature on the short-time ratings of the various types of



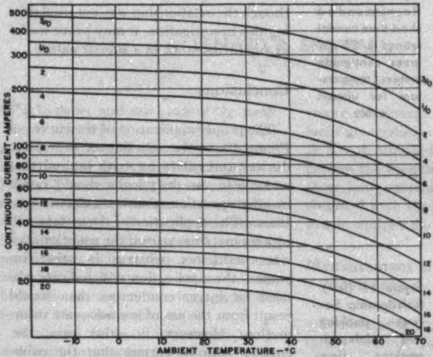


Figure 7 (top). Effect of ambient temperature on temperature–time curves of one type of cable. *AN* size number 8

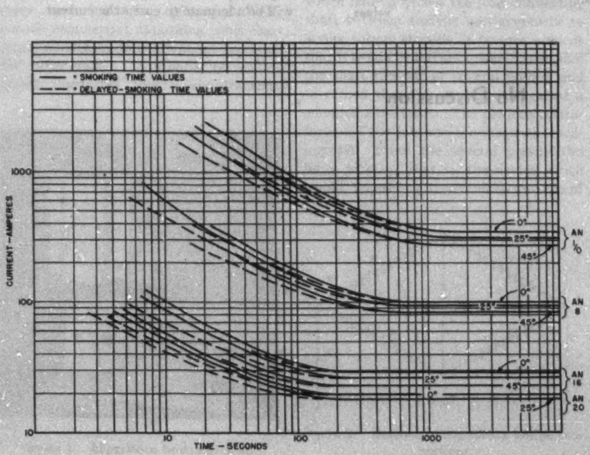
Figure 8 (left). Effect of ambient temperature on continuous current ratings of aircraft cable

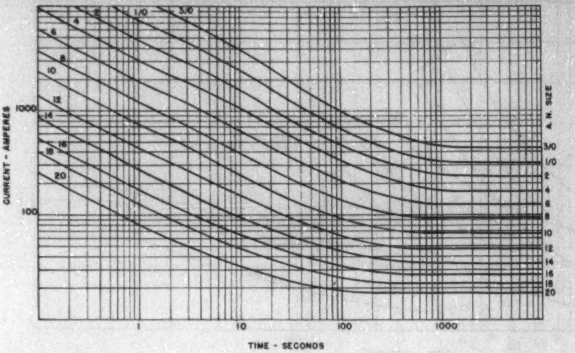
Figure 9 (below). Effect of ambient temperature on the short-time current ratings of aircraft cable



cables. Figure 9 presents the average results of smoking-time and delayed smoking-time as a function of current for various ambient temperatures. Data were not taken for periods of time less than five seconds because of limitations of accuracy in control and measurement.

Using the data of Figures 8 and 9 a set of curves was prepared showing the maximum safe current that a conductor could carry for a given period of time when in an ambient temperature of 25 degrees centigrade. This is shown in Figure 10. The shape of the curves for *AN* sizes numbers 0, 8, 16, and 20 for times between 2,000 seconds and five seconds is based on experimental data. Below one second the curves are based on calculation of the heat energy required on a no-loss basis to raise the temperature of the wire size in question to a value of 150 degrees centigrade. A conductor temperature of 150 degrees centigrade was used as the maximum safe temperature for the shorter time periods. Each curve, from 2,000 seconds to five seconds, is extrapolated from five seconds to one second to join the calculated curve at this point. The curves for other wire sizes were drawn with the same shape as that for *AN* sizes numbers 0, 8, 16, and 20; and asymptotic to the lines representing maximum continuous currents for the respective cable sizes and ambient temperature as found on Figure 8.

It is important that attention be directed to the fact that the curves of Figures 6, 8, 9, and 10 are values averaged from six types of *AN* aircraft cable used for this investigation. These values do not exceed by more than six per cent those obtained for the cables most susceptible to smoking. Therefore, the general application of these curves to all existing



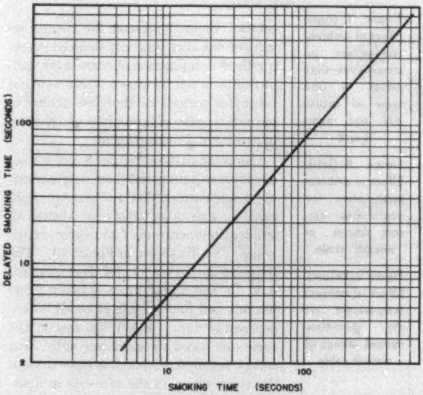


Figure 10 (top). Recommended short-time current ratings in 25 degrees centigrade ambient temperature for aircraft cable

Figure 11 (left). Relationship between smoking and delayed-smoking time values

types of *AN* cable should not be made without an allowance for this six per cent variation. However, it is recommended that consideration be given to the use of Figure 10 as a standard for the manufacture of aircraft cable.

During the course of this investigation, it was noted that a relationship existed between the delayed smoking time and smoking time data. This is shown in Figure 11, or by the equation

$$T_d = 0.46 T_s^{1.12}$$

where T_d is the delayed smoking time and T_s the smoking time. Data for this curve were obtained from the numerous observations made during the investigation. However, this curve is satisfactory for intervals up to five minutes; for longer periods of application the continuous current rating should be used. Although the relationship was not used during this investigation, it may prove useful in any future work of a similar nature.

Conclusions

The proper application of the curves of Figure 10 to the selection of protective devices and cables for both intermittent and continuous duty loads should result in safer operation of aircraft electric systems. The application of these data will in some instances permit the use of smaller size conductors, whereas in other instances the application will indicate the need for larger conductors than would result from the use of less adequate information. However, in either case, the engineer can be certain that the cable will be adequate to carry the current.

No Discussion

Some Oscillographic Methods of Investigating Mechanical and Hydraulic Conditions During Operation of Hydroelectric Units

LENARD R. ENGVALL
ASSOCIATE AIEE

THIS paper outlines some of the methods by which a magnetic oscillograph, with auxiliary equipment, has been used at the Grand Coulee Power Plant, Columbia Basin Project, to obtain and co-ordinate information about hydroelectric units which can not be obtained from ordinary indicating and recording instruments. Quantities measured and recorded include mechanical movement, hydraulic pressures, bearing loads, and turbine vibration and noise.

A special form of impedance bridge was built to measure mechanical movement and hydraulic pressure. Well-known commercial apparatus, plus electronic amplifiers, were adapted to register the other values. A number of oscillograms illustrates how a simultaneous record of several related quantites can facilitate analysis of a particular problem. It is not intended to imply that a new process has been developed, but rather to show how valuable information can be obtained with the help of comparatively simple equipment.

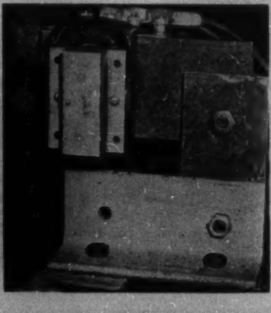

Figure 1. Impedance bridge pick-up

Measurement of Mechanical Movement

While attempting to adjust a Kingsbury thrust bearing, following some trouble which had subjected the long connecting shaft between turbine and generator to severe torque stresses, it became evident that it would be advantageous to measure the shaft run-out at several points, and to record these measurements against a common time base. The obvious instrument for the job was the magnetic oscillograph. From the several possibilities for a pick-up, that is, the device which would transform mechanical movement into electrical quantities, the impedance bridge was chosen as the most suitable because it was simple and rugged, and could be made sufficiently sensitive with out electronic amplification. Also important was the fact that no mechanical connection to the moving member was needed. Figure 1 shows the appearance and physical arrangements of the pick-up, which is shown in position for use in measuring movement of 44-inch diameter steel shaft. Coils are wound on laminated core of one square inch cross section. Two coils on each core are connected electrically in diagonally opposite sides of bridge circuit.

The particular form used consists of four identical coils connected in a bridge circuit and placed in pairs on two iron cores. One core is held firmly on a minutely adjustable support a little less than one-eighth inch from the moving member of which the record is to be taken, so that that member completes the magnetic circuit and varies its reluctance. The other, for convenience, is mounted on the same frame, but its magnetic circuit is entirely independent, and includes a fixed and approximately equal

Paper 49-204, recommended by the AIEE Instruments and Measurements and Power Generation Committees and approved by the AIEE Technical Program Committee for presentation at the AIEE Pacific General Meeting, San Francisco, Calif., August 23-26, 1949. Manuscript submitted May 9, 1949; made available for printing July 14, 1949.

Lenard R. Engvall is with the United States Department of the Interior, Coulee Dam, Wash.

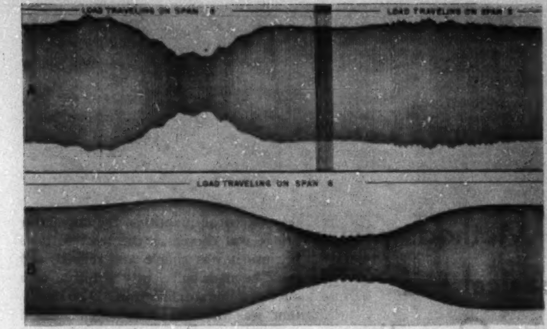

Figure 4. Records of deflection of center of 150-foot span on multiple-arch reinforced-concrete bridge while 35-ton load is passing over

Curve A was taken with load traveling 25 miles per hour. Maximum deflection downward is 0.060 inch; upward 0.017 inch. Curve B was taken with load traveling 5 miles per hour. Maximum deflection downward is 0.069 inch, upward 0.012 inch. Maximum design loading is 40 tons, concentrated. Pick-up located at center of span 6

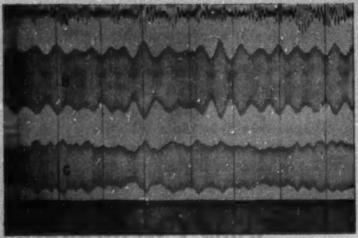

Figure 6. Record of hydraulic conditions in relation to shaft run-out on 150,000-horsepower turbine, 0.40 gate, 50,000-kw load

Maximum pressure change in scroll case, trace B, is 16 pounds per square inch; in draft tube, trace D, 7 pounds. Shaft run-out, trace C, at approximate middle is 0.007 inch

air gap. Electrical connections are shown in Figure 2, showing coils 1 and 3 mounted on one laminated iron core, coils 2 and 4 on the other.

A low, constant, 60-cycle a-c potential is applied to one pair of terminals of the bridge and an oscillograph galvanometer connected to the "neutral," or output, terminals. Actually, the device functions because it is always unbalanced, the adjustment of the variable air gap being made either greater or lesser than the fixed air gap so that the neutral point is not crossed. The galvanometer then indicates the amount of unbalance, and the peak-to-peak deflection of the trace on the record is a measure of the movement being studied.

It should be kept in mind that in the oscillograms shown in this paper which were obtained by the use of an impedance bridge, only a change in envelope width indicates a change in the quantity measured. This relation is calibrated. The actual width of the envelope has little significance. While the relation between movement and deflection is not exactly linear, it is sufficiently close to it so that the error can be disregarded for most purposes. A change of one inch in the width of the envelope on the original record indicates a movement of approximately 0.015 inch

Figure 3 shows a typical record of a shaft in normal operation on 108,000-kw machine turning 120 rpm. The distance between top and bottom pickups is about 62 feet. Trace A shows a horizontal movement of 0.003 inch at a point just below the thrust bearing, that is, a run-out of 0.0015 inch either way from the average position. Trace B is taken at a point just below the rotor and shows a run-out of 0.004 inch; trace C is taken at the intermediate coupling, and trace D just above the turbine bearing, indicating run-outs of 0.0055 and 0.0035 inch respectively.

Figure 5. Record of hydraulic conditions in relation to generator output on 150,000-horsepower turbine, .046 gate, 60,000-kw load

Maximum pressure change in scroll case, trace B, is 15.5 pounds per square inch; in draft tube, trace C, about 10 pounds per square inch. Variation in output, trace D, is about 2 per cent

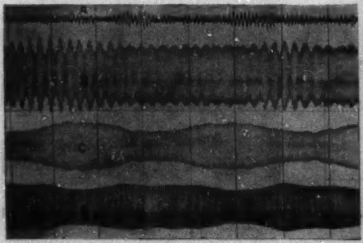

Figure 7. Record of pressure build-up in scroll case of 150,000-horsepower turbine in relation to generator electrical quantities during load rejection test

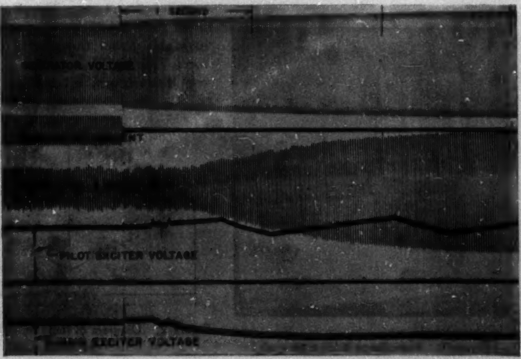
Pressure increased 38 pounds per square inch. Penstock is 18 feet in diameter and about 340 feet long



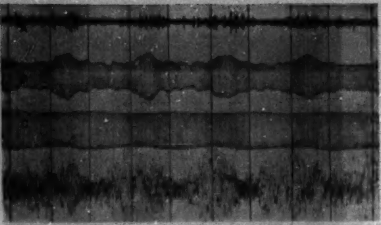


Figure 8. Record of noise and vibration associated with pressure changes in hydraulic turbine

One might logically expect the whole shaft to move in the same direction at the same time. This it does not do, however, as may be seen from the curve *X-Y*, drawn through the maximum point in each trace, which indicates a phase difference of about 120 degrees between the top and bottom. Similar records have been of assistance in balancing the rotors on these slow speed machines.

Another interesting application is the use of this apparatus to check the deflection and vibration of one span of a multiple-arch reinforced-concrete bridge under a rapidly moving load. Figure 4 shows the deflection at the center of the span as a 35-ton load passed over at speeds of 25 and 5 miles per hour, respectively. Maximum deflection from no load was 0.068 inch. Attempts had been made to obtain the same information by reading indicating instruments, but the changes were too rapid to obtain satisfactory results.

Measurement of Hydraulic Pressure

Since there has been reason for considerable curiosity about the performance of the turbines at the Grand Coulee Power Plant, the next logical step was the investigation of hydraulic pressures under various conditions of operation. The impedance bridge also lent itself admirably to this application. To the end of a Bourdon tube, taken from an ordinary pressure gauge, is attached a small piece of sheet steel which becomes the moving member of the bridge. This type of pick-up is somewhat limited in frequency response, the particular ones constructed having a natural frequency of a little over 20 cycles per second. Where much higher frequency measurements are necessary, a diaphragm type of gauge probably would give better results. Such pick-ups connected to show the scroll case and draft tube pressures gave a good picture of how the two varied at different loads, and to what extent disturbances on one side of the turbine runner appeared on the other side. In Figure 5, trace A shows the crown plate vibration, trace B scroll case pressure, trace C draft tube pressure, and trace D generator output. A swing of about two per cent can be detected in the output, but it does not appear to be synchronized with the hydraulic variations.

At certain loads, interesting relations have been found between shaft run-out and draft tube pressures. An example of this appears in Figure 6, where traces C and D represent shaft run-out and draft tube pressure, respectively. It is evident that these pressure changes, which seem to have definite cycles of about three revolutions each, and may be the result of vortex movements, are powerful enough to pull the shaft an appreciable amount out of line.

Figure 7 shows a record of pressure build-up in the scroll case resulting from governor action during a load rejection test when 132 megawatts were dropped.

Measurement of Noise and Vibration

A device which has been adapted to yield additional information is the ordinary radio loud-speaker of the permanent-magnet field type. By weighting and cushion-mounting the frame so that its movement is negligible, and mechanically coupling the moving coil or cone to the member being studied, an alternating current is produced which is generally indicative of its movement. The output is usually sufficient to be easily recorded on a fairly sensitive galvanometer. Unfortunately, it is not readily calibrated, since the output voltage is dependent on frequency as well as amplitude. Nevertheless, it is valuable for comparison. Noise, transmitted by air, can be similarly recorded. An example of a record on which are shown these quantities is given in Figure 8. Trace A indicates vibration of the turbine cover plate, as picked up by the loud-speaker, traces B and C show pressures in the scroll case and draft tube respectively, and trace D represents noise coming from the draft tube.

Measurement of Bearing Loads

Another type of pick-up device has provided considerable information about bearings. On each jack pin supporting a segment of the Kingsbury thrust bearing on the main units at the Grand Coulee Power Plant, are mounted two Baldwin-Southwark type *SR-4* strain gauges. These are used in the initial installation to secure equal loading on all the bearing shoes. However their usefulness does not end there. By connecting each pair in the well-known Wheatstone bridge circuit, and applying an a-c potential, a small output is obtained across the midpoints whenever the bridge is adjusted a little off balance. This output must be amplified before the ordinary oscillograph can record it, and this was done by using a multiple channel electronic amplifier of conventional design. By means of a vacuum tube voltmeter, the over-all response was calibrated, and the change in bearing loading measured.

Examples of the type of records obtained are shown in Figures 9 and 10. It is evident from Figure 9, that in spite of the extreme care with which these bearing runners are finished, this one had two high spots, but it is otherwise typical of normal operation. Figure 10 shows the variation in total loading assumed to be caused by hydraulic disturbances. Measurements indicate a total load change of 192,000 pounds or 96,000 pounds more or

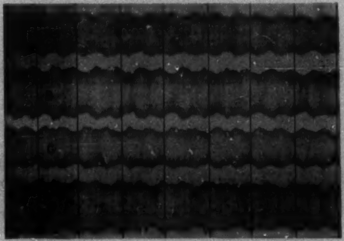

Figure 9. Record of load changes on alternate shoes of a Kingsbury thrust bearing, on a 108,000-kw generator turning 120 rpm, full load. Average load change per shoe is 7,500 pounds

less than the average. This amounts to six per cent of the 1,430,000 pounds rotating weight.

The apparatus also has been used for a determination of the hydraulic thrust, which for the particular unit on which these records were taken amounts to as much as 280,000 pounds upward, reducing the bearing load to 80 per cent of the maximum.

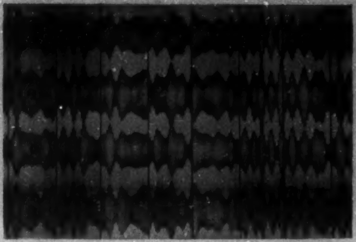

Figure 10 (right). Record of load changes on 4 of 8 shoes of Kingsbury thrust bearing, on a 108-megawatt generator, 25-megawatt load. Trace A indicates maximum load change of 19,000 pounds, trace B 27,000 pounds, traces C and D 25,000 pounds

Conclusion

The foregoing examples have been selected from the files of the United States Bureau of Reclamation, to show the variety of information which can be readily recorded and is likely to be of value at any hydroelectric station. Probably many instances will occur to operating and test engineers where similar data would be helpful. Since the oscillograph first came into general use, its value for testing electrical circuits on all kinds of power equipment has been recognized. The ease with which it can record mechanical conditions as well, such as shaft movements, bearing pressures, hydraulic or steam pressures, vibration, and many others, and the low cost and simplicity of the auxiliary apparatus required should make it of equal value to operating and maintenance personnel.

No Discussion

Deionization Time of High-Voltage Fault-Arc Paths

EVERETT J. HARRINGTON
ASSOCIATE AIEE

E. C. STARR
FELLOW AIEE

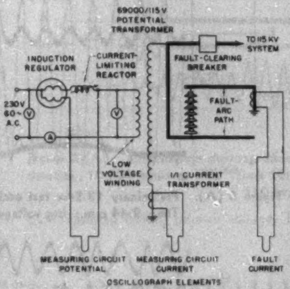
AUTOMATIC reclosing of circuit breakers in high-voltage transmission lines can materially increase system transient stability limits provided reclosure can be accomplished very rapidly. In case of temporary faults resulting from lightning, the minimum time in which this reclosure can be accomplished successfully is determined mainly by three factors:

1. Circuit breaker limitations.
2. Total duration of lightning stroke or its multiple components.
3. Deionization time of the fault-arc path and its consequent recovery of dielectric strength.

With regard to the first factor, modern circuit breakers have been developed to the point where minimum reclosing time is not expected to be limited by them. The second factor is one which may very well be the determining item. Inasmuch as this is a natural phenomenon, limitations which it may impose can be determined only by extensive experience with high-speed reclosing combined with field data on lightning-stroke duration. The rather meager data available at present on multiple lightning strokes to lines indicate that approximately 10 per cent persist for more than 0.25 second or 15 cycles (from initiation of fault) on a 60-cycle system.[1]

The third factor is one on which little data are available, particularly in regard to deionization time of fault-arc paths on 115- and 230-kv transmission lines. In order that reclosure be successful, dielectric recovery of the ionized fault-arc path must have proceeded to the point where re-application of system voltage will not produce sufficient current through the arc path to maintain ionization. If for a given recovery voltage and length of arc path the minimum current to maintain ionization is known, the minimum time in which successful reclosure can be accomplished can be determined provided the high-voltage resistance of the arc path in respect to time can be obtained.

Figure 1. Schematic diagram of 115-kv test circuit



A method has been developed for determining the resistance and dielectric recovery rate of the arc path after fault-current interruption. Field tests on a 115-kv system (at the J. D. Ross Substation of the Bonneville Power Administration) were performed, and data obtained on deionization of fault-arc paths produced by single-phase faults having equivalent 3-phase magnitudes from 750 to 3,000 megavolt-amperes. The effects of fault magnitude and duration are shown, and additional tests are proposed.

Test Circuit

In order to determine the dielectric strength of the fault-arc path during the period subsequent to fault-current interruption, it is essential that the high-voltage measuring circuit have negligible effect upon the resistance of the ionized path and its rate of dielectric recovery.

Figure 1 shows the circuit used in the 115-kv tests. A measuring potential was applied to the arc path from a high-impedance source consisting of a 69,000/-115-volt potential transformer whose low-voltage winding was energized from a 60-cycle a-c source through a current-limit-

Manuscript submitted May 25, 1949; made available for printing June 29, 1949.

EVERETT J. HARRINGTON is with the United States Department of the Interior, Bonneville Power Administration, Portland, Oreg.; and E. C. STARR is Professor of Electrical Engineering at Oregon State College, Corvallis, Oreg.

The authors wish to acknowledge the assistance of George Anderson, Richard Dietrich, and the Pacific Electric Manufacturing Corporation in the preparation of this paper.

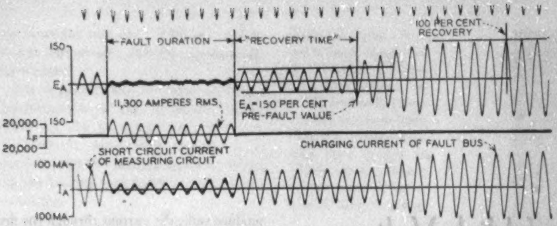

Figure 3. Typical recovery oscillogram 8.5-cycle fault; 11,300 amperes rms. Time, 10:20 p.m.; fault megavolt-amperes, 2,200; bus voltage, 110 kv; arc location, air

E_A=measuring circuit, primary voltage; I_F=fault current; I_A=measuring circuit, secondary current

ing reactor. This reactor was adjusted as follows: with the transformer high-voltage winding open circuited (test bus capacitive excitation load only), the induction regulator was adjusted to give 69 kv across the transformer high-voltage winding. This winding was then short circuited, and the reactor adjusted so as to limit the current in the winding to less than 100 milliamperes. This adjusting procedure was repeated until the desired open-circuit voltage and short-circuited current were obtained.

Establishment of the fault arc short circuits the transformer high-voltage winding, and the oscillograph element across the low-voltage winding indicates a potential essentially equal to the transformer and its supply lead impedance drop. This drop is small compared to that across the current-limiting reactor. After fault-current interruption, deionization of the arc path and consequent increase in its resistance progressively limits the transformer current and the voltage across its terminals rises, reaching normal value when conduction through the arc path ceases. This voltage is then a measure of arc-path conductivity. Under ideal test conditions the current in the transformer high-voltage winding would drop to zero when arc-path conduction ceases, and normal voltage is re-established.

During the tests described herein, cessation of current flow in the arc path did not result in zero current through the transformer high-voltage winding due to the presence of appreciable capacitance in the form of bus work, insulators, and circuit breaker bushings. The charging current at normal voltage to this equipment was actually greater than the short-circuit current; consequently dielectric recovery of the arc path resulted in a rise of measuring-circuit current. This effect plus the fact that the measuring-circuit potential recorded was actually the vector sum of the arc-path resistance and transformer and lead impedance drops prevent simple direct calculation of arc-path resistance from these data. Figure 2 is an oscillogram showing the time of response of the measuring circuit only. This was the tained by opening a short circuit across ob- high-voltage winding of the potential transformer by means of a 115-kv oil circuit breaker. From this it may be seen that the natural recovery period of the measuring circuit was slightly more than one cycle which is less than the recovery time of any of the phenomena investigated.

Another test circuit has been designed which will permit recording of voltage

Figure 4. Typical arcing fault on test bus

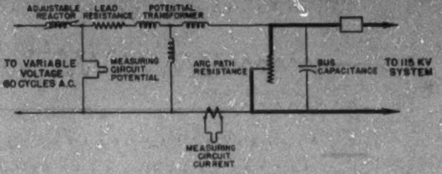
Figure 7. Equivalent measuring circuit



drop across the arc path only and conduction current through this path only. This circuit will be described in subsequent paragraphs. It was not used during these tests, as they were performed in conjunction with a group of scheduled circuit breaker tests, and the time available for preparation did not permit construction of the necessary equipment.

The records obtained, while not ideal do permit dielectric recovery of the arc path to be observed in terms of measuring circuit potential. Figure 3 is typical of these oscillographic records. E_A is the measuring-circuit potential. Prior to application of fault current, the fault bus was grounded by a fuse wire; consequently the amplitude of the trace E_A is proportional to the transformer and lead impedance drops until the fault circuit breaker is closed. At this time the potential E_A drops to a low value due to reduction in station-service voltage combined with a phase difference in fault-producing potential. Immediately after fault interruption this voltage returns to the prefault value and remains so for several cycles, thereby indicating low arc-path resistance. After approximately 7$^1/_4$ cycles in this case, the voltage begins to rise and continues to do so until full voltage is reached. At this point dielectric recovery may be considered nearly complete, as approximately 69 kv is being applied across the arc path with practically no conduction resulting.

Before using the circuit just described, it was first necessary to establish proof that currents in the order of 100 milliamperes or less would not prolong dielectric recovery of the arc path. There also was some question as to the validity of initiating fault arcs by small diameter copper wire. To determine these effects, preliminary tests at 13.8 kv were performed using a very similar circuit except that the current-limiting impedance was in the form of capacitors rather than a reactor. Use of capacitors necessitates precautions to prevent series resonance and ferro-resonant conditions in circuit.

Test Procedure

The 13.8-kv preliminary tests were performed by closing into a fault established by a fuse wire across a 15-kv insulator or a comparable gap with subsequent automatic tripping of the fault circuit breaker and interruption of the arc. Faults were initiated by copper fuse wires varying in size from number 19 to number 33 American wire gauge. Fault currents of 600 and 1,600 amperes were used. Magnitude of the measuring-circuit current was varied from approximately 2 milliamperes to 140 milliamperes. All pertinent currents and voltages were oscillographically recorded.

The 115-kv tests were all single-phase-to-ground faults. All faults were initi-

ated by number 33 American wire gauge, copper wire and were arranged to cascade a 7-unit string of suspension insulators or to bridge a vertical gap formed by two strain busses spaced 46.5 inches apart (see Figure 4), except that two faults were produced between busses 14 feet apart. Fault megavolt-amperes varied from approximately 750 to 3,000 (4,000 to 16,000 amperes rms), and fault duration varied from a fraction of a cycle to a maximum of 10 cycles.

Data Obtained

A total of 28 tests was performed at 13.8 kv from which 21 useful oscillograms were obtained. These data enable conclusions to be drawn regarding effect of initiating faults by fuse wire and the effect of measuring-circuit current upon deionization of the arc path.

A total of 48 tests was performed on the 115-kv system resulting in 41 useful oscillograms. Ultra-rapid motion pictures (3,000 frames per second) of 13 of the fault arcs were taken. Single frames from two of these films are reproduced in Figure 12.

Discussion of Results

The 13.8-kv preliminary tests indicated variation of wire size from number 19 to 33 produced no appreciable change in deionization time. In all of the 13.8-kv tests recovery was very rapid, never exceeding three cycles from current interruption to full recovery of the measuring potential. From this it was concluded that the presence of metallic vapor from the initiating fuse had very little effect upon dielectric recovery.

Variation of measuring-circuit current from 2 to 140 milliamperes during the preliminary tests produced no noticeable change in deionization time. As a result, it was decided to make the 115-kv tests using number 33 copper wire to initiate the fault arc and a measuring-circuit current of approximately 70 milliamperes.

Variation of fault current from approximately 600 amperes to 1,600 amperes produced only a small change in deionization time at 13.8 kv. Figure 5 shows typical oscillograms obtained during these tests. It will be noted in Figure 5(A) that full recovery occurred in approximately 1.25 cycles with a fault current of 675 amperes rms. Figure 5(B) indicates full recovery in approximately two cycles with a fault current of 1,540 amperes. Apparently low-energy faults produce such small quantities of ionized gas that deionization is accomplished in a very brief interval of time.

In interpreting the data obtained during the 115-kv tests, it was necessary to select a time after fault-current interruption as the point where dielectric recovery had progressed sufficiently that re-ignition would not occur upon reapplication of full voltage. This point was arbitrarily chosen as being the point where the measuring-circuit potential had recovered to 150 per cent of the value attained immediately after fault interruption. For the circuit used, this point corresponds to an arc-path resistance of approximately 0.25 megohm. It is believed, however, that system voltage (69 kv to ground) could not maintain ionization through a normal fault path whose resistance is in excess of 50,000 ohms; therefore the foregoing criterion is considered conservative. The time from fault-current interruption to this point is hereafter referred to as

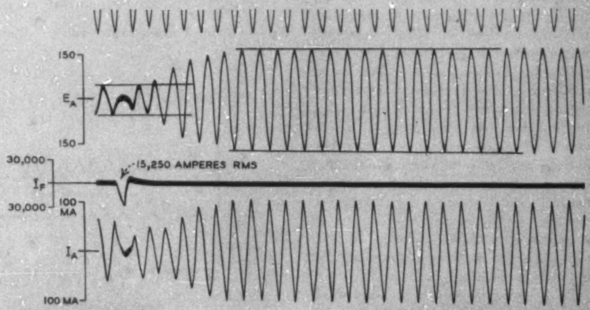

Figure 10. Oscillogram showing very rapid recovery after fault of 0.75-cycle duration, 15,250 amperes rms. Time 3:20 p.m., fault megavolt-amperes 2,920, bus voltage 110.5 kv, arc location, air

"recovery time." This recovery time has been selected to give a consistent basis for recovery comparison and does not necessarily represent minimum time for successful reclosure.

Figure 6 is a curve of arc-path resistance shown as a function of measuring-circuit potential. This curve was obtained by setting the equivalent measuring circuit, Figure 7, up on an a-c calculating board. Arc-path resistances necessary to give currents and voltages corresponding to instantaneous values recorded on the oscillogram for test number *PE-4C* throughout the recovery period were determined directly thus eliminating much calculation. This curve shows that the path resistance is approximately 50,000 ohms at the point where the measuring potential first begins to increase. An increase in measuring potential of 150 per cent corresponds to a path resistance of approximately 0.25 megohms.

Figures 8, 9, and 10 are typical of the records obtained during the 115-kv tests. Note that in Figure 8 the measuring-circuit potential indicates a relatively low resistance of the arc path for a period of several cycles after fault interruption, after which a fairly uniform increase in path resistance occurs until conduction ceases and the measuring potential becomes a maximum. Figure 9 indicates somewhat the same conditions except that recovery is interrupted as evidenced by sudden collapse of the measuring potential. These interruptions and subsequent recoveries are probably the result of eddying of gases in the ionized column due to convection currents. Whether such recovery interruptions represent a decrease in resistance sufficient to permit re-ignition is a matter that still has to be determined. It is believed that re-ignition will not occur as a result of such interruptions as may occur after quite a few cycles of dead time; however, in order to be conservative, recovery times here-in were, in the cases where such interruptions occurred, measured from fault-current interruption to the measuring-voltage crest succeeding the last dielectric interruption.

Deionization Time of Arc Path

Figure 11 shows the recovery times obtained for three values of fault megavolt-amperes. Perhaps the most significant fact disclosed by this is that recovery time is to a great extent determined by fault-current duration. Faults greater than 2,000 megavolt-amperes resulted in somewhat greater recovery time, but in all cases a decrease in fault duration shortens the recovery time. Figures 3 and 8(A) serve to illustrate this effect. In Figure 3 a fault current of 11,300 amperes rms lasting for 8.6 cycles gave a recovery time of 8.2 cycles, while in Figure 8 a fault current of approximately the same magnitude but of only 1.6-cycle duration required a recovery time of only 4.2 cycles. In Figures 8(B) and 9(A) it may be seen that relatively low currents of long duration required long recovery times, while in Figures 9(B) and 10, high currents of very short duration resulted in very rapid path deionization. The reason recovery is rapid after very brief fault durations is quite apparent from study of a series of ultra-rapid (3,000 frames per second) motion pictures taken of some of the arcs. In the cases of long fault duration, even at relatively low currents, very large volumes of luminous gases are created which cool and break up relatively slowly; furthermore, magnetic forces caused the arc to progress along the lower fault bus in one direction and along the upper fault bus in the opposite direction, see Figure 12 (left). The hot gases produced along the lower bus rise toward the upper bus as a large billowing mass prolonging con-

duction between buses. Short periods of fault current produced a vertical column of luminous gas, see Figure 12 (right) of relatively small cross section which, upon current interruption, broke into segments as it rose and rapidly disappeared.

Circuit Breaker Reclosing Time

The results of these tests should not be taken as conclusive in respect to absolute minimum time of reclosure in practice. They are considered, however, as being indicative and possibly somewhat conservative as to 3-phase reclosing times applicable to 115-kv grounded-neutral systems. The curves of Figure 11 indicate that large magnitude faults cleared in 4.5 cycles might require as much as 12.5 to 14.5 cycles of dead time for path deionization, thereby permitting reclosure 17 to 19 cycles after inception of the fault. This is, of course, based upon the assumption that no additional lightning strokes occur after or immediately prior to reclosing.

Additional Tests

In order that definite reclosing times may be established, much additional data are necessary. Further tests on the Bonneville Power Administration 115- and 230-kv systems are planned; moreover, it is proposed that manufacturers having suitable facilities incorporate such tests as a part of routine and special high-voltage circuit breaker tests. It is believed that these investigations should be organized to provide more data similar to that presented in this paper. In addition, a series of reclosing tests should be performed in an attempt to establish what arc-path resistance is necessary to permit successful reclosure, and to determine whether the dielectric recovery interruptions discussed previously are of such a nature as to permit re-ignition if reclosure is made during that period.

Figure 13 is a schematic diagram of an improved test circuit which probably will be used for future tests on the Bonneville Power Administration system. Voltage across the arc path will probably be taken from a bushing-capacitance tap and applied to the oscillograph through an amplifier.[2] Fault current will be recorded from the secondary of a suitable step-down current transformer. After the fault current ceases, the measuring-circuit current through the arc path will be in the order of milliamperes, so in order to obtain sufficient deflection on the oscillograph element a one-to-one ratio current transformer will be used. During flow of fault current this transformer will be by-passed by the short-circuiting contactor. Action of this protective circuit is as follows:

> Prior to fault-current application the momentary switch is closed, energizing the closing coil of the snap-action switch which, upon reclosing, causes the short-circuiting contactor to pick up and by-pass the one-to-one ratio current transformer. The momentary switch is then released and the fault applied. Flow of fault current through coil "B" causes the snap-action switch to open, thereby de-energizing the short-circuiting contactor pick-up coil. This contactor is prevented from opening by flow of fault current through holding coil "A." Interruption of fault current permits the short-circuiting contactor to open and thus

* Taken as the time from interruption of fault current until measuring-circuit potential has recovered to 150 per cent of the value attained immediately after fault interruption.

** In cases where dielectric recovery was characterized by one or more interruptions, this alternate deionization time was taken as the time from interruption of fault current until the first measuring-circuit voltage crest after the last recovery interruption.

energize the oscillograph element recording measuring-circuit current through the arc path during the recovery period.

This circuit should permit recording of the arc-path voltage drop and current from which instantaneous values of arc-path resistance may be computed throughout most of the recovery period.

Conclusions

1. A method of obtaining useful data on fault-arc deionization time has been devised. It is hoped this will lead to the obtaining of additional data which, when summarized, will enable minimum reclosing times for 115- and 230-kv circuits to be established.

2. Deionization time of arc path is principally a function of fault duration.

3. On the 115-kv system variation of fault magnitude from 750 to 1,700 megavolt-amperes had very little influence on maximum deionization times of the arc path. For fault magnitudes of 2,000 to 3,000 megavolt-amperes, maximum deionization times were increased somewhat.

4. Although data contained herein are not conclusive, the indication is that for fault clearing times of four cycles 3-phase reclosure may be feasible after 10 cycles of dead time. Reduction of fault duration to three cycles indicates only seven cycles of dead time; while two cycles of fault duration indicate approximately five cycles of dead time prior to reclosure on a 115-kv system.

This serves to illustrate the importance of high-speed relaying and fast circuit breakers on systems contemplating ultra-fast reclosing.

5. While decrease in fault-clearing time is always desirable and future developments may make this possible, it may not be feasible to decrease reclosing time below a certain limit as determined by multiple-lightning-stroke phenomena.

6. The presence of insulator strings in the arc path does not appreciably decrease deionization time. The use of small diameter copper wire for fault initiation does not appreciably delay deionization of the arc path.

Discussion

T. E. Browne, Jr. (Westinghouse Research Laboratory, East Pittsburgh, Pa.): This paper describes an interesting experimental study of an important but heretofore little understood phenomenon, the post-arc dielectric recovery of long open-air arc trails, and is to be commended as a pioneering effort. As such, it is understandable that these early results are not entirely satisfactory or conclusive, but they do give some new insight into the behavior of fault-arc paths.

In particular the authors speak of deionization, rise of high-voltage resistance, and dielectric recovery of the fault-arc paths as if these expressions were virtually synonomous. Also, in interpreting their results, the authors appear to overlook significant differences in meaning between the measured arc path resistances and the inferred dielectric strengths of the arc paths. They speak of and plot an arbitrarily defined "recovery time" or "deionization time" based on use of arc resistance, without showing how this is related to the desired practical quantity, time for recovery of sufficient dielectric strength to permit successful circuit breaker reclosure.

The basic concepts involved in the dielectric recovery of a long arc space were discussed rather completely by Dr. Slepian[1] nearly 20 years ago. The long-time scale involved here, many cycles for dielectric recovery of long open-air power arcs compared with a fraction of a half-cycle for circuit breaker arcs, does not really alter the phenomena so long as the arc can be considered to be homogeneous throughout its length. Dr. Slepian pointed out that the stable existence of an arc column depended upon a balance between power loss, *W*, from the hot ionized arc space due to cooling and ion diffusion, and the electric power input e_a times *I*. The dielectric strength of an arc space was defined as the voltage required to maintain this balance and so to hold the conductance of the arc space constant. In terms of the arc resistance, *R*, this can be very simply expressed by the equation

$$\frac{E_d^2}{R}=W_0, \text{ or } E_d=\sqrt{RW_0}$$

when E_d is the dielectric strength corresponding to the arc space resistance, *R*, and also to the existing rate of energy loss from the arc space, W_0. It is clear that E_d is a breakdown voltage, since any sustained increase in applied voltage above E_d will cause the arc space energy to increase, resulting in lowered resistance and cumulatively increasing current flow.

In assuming correspondence between the dielectric strength and the resistance of a long arc space, the authors have treated W_0, the power dissipation from the arc space, as a constant. If, as the writer believes, W_0 also is a variable, it is equally as important as *R* in determining the dielectric strength of the arc space. It is true that effective dielectric recovery of an arc space will accompany a rise of arc space resistance to and above some high value, but the actual magnitude of this critical resistance is entirely dependent upon the existing level of W_0. Therefore, in the absence of knowledge about W_0, the arbitrary selection of some level of arc space resistance as indicating effective "deionization," or dielectric recovery of the arc space would appear to be relatively meaningless. In particular, one would expect W_0 to be quite largely determined by both the magnitude and duration of the fault-arc current preceding the recovery period, since these quantities largely affect the actual arc path length and diameter, the degree of turbulence in the immediately surrounding air, and the related temperature and ion density gradients during the recovery period. Thus, it is not at all surprising that plots versus fault current and fault duration of "deionization time" based on rise of arc resistance alone, Figure 11 of this paper, do not agree with the plots of directly observed dielectric recovery times in the paper by Boisseau, Wyman, and Skeats.[2]

Another consideration which may lessen the practical value of resistance measurements is the observed inhomogeneity of the arc space, especially toward the end of the recovery period, as reported by the authors, and shown in Figures 4(A) and 12(A) in the paper by Boisseau, Wyman, and Skeats. If this apparent "breaking up" of the arc residue should result in virtual loss of conductance by some fraction of the arc path only, this fraction might be too short to sustain the full restored voltage even though the total resistance of the arc path may have already approached infinity. This appears to be the explanation of the so-called "recovery interruptions" reported in the paper and illustrated by the oscillograms of Figure 9. In Figure 9(A) there is clearly a dielectric failure with sudden discharge of the bus capacitance at about 60-kv rms restored voltage somewhat later than the point defined as the end of the deionization time, followed by three other successive breakdowns at still lower voltages. These show that the dielectric recovery was influenced by the measuring circuit and was not accurately indicated by the resistance measurement. In Figure 9(B) the discharges apparently begin much earlier, occurring both before and after the specified deionization time.

In view of these observations, it is the opinion of the writer that resistance rise measurements are interesting and of value in aiding our knowledge of the nature and behavior of post-fault arc trails but that they cannot safely be substituted for actual dielectric tests in determining limits for circuit breaker reclosing times.

A further comment with regard to Figure 11 is that the lines, if drawn through the means of the points instead of through extreme points in the badly scattered groups, would have slopes roughly proportional to the arc current magnitudes, indicating that the resistance rise time may be more accurately said to depend upon the product of fault current and fault duration rather than upon duration alone.

With regard to future studies, the writer wonders whether the authors have considered the use of a direct rather than an alternating source of voltage in the resistance measuring circuit.

D. M. Umphrey (Pacific Electric Manufacturing Corporation, San Francisco, Calif): The authors have made a valuable contribution to fundamental knowledge concerning the high-speed reclosing of transmission circuits. It has been difficult in the past to isolate the various factors which control minimum reclosing times. For example, this paper presents the first quantitative information, to my knowledge, regarding the effect of fault arc duration on minimum reclosing time. The minimum permissible de-energized time for successful staged reclosing tests has varied from as low as six to as high as 16 cycles. There was only speculation as to whether the discrepancy was caused by air velocity, influence of metal vapor from fuse wire, humidity, time of arc duration, the proximity of porcelain insulating surfaces, or perhaps capacitively induced currents in the fault arc path during the supposedly de-energized period. In all such cases with which I am familiar, shorter fault arcing time permitted faster reclosing. This would be expected from the information supplied by the authors.

It is interesting also to note that metal vapor from the fuse wire has little effect on deionizing time. This has been a controversial point for some time.

The principle reason in the past for clearing faults in the shortest possible time on high-voltage circuits was to minimize the direct effect on transient stability. However, there now appears to be another reason of nearly equal importance, in that the time consumed by fault clearing equipment such as relays and circuit breakers, can seriously influence the shortest permissible reclosing time. The effect of multiple lightning discharges on high-speed reclosing may present a rather serious problem in addition to that of limiting reclosing speed as indicated by the authors. During the de-energized period in which deionization must take place, circuit breakers at the line terminals will receive an impulse with every repetitive stroke. Thus the circuit breaker arc rupturing equipment will be subjected to a series of impulses throughout its opening and closing strokes. I understand that such repetitive impulses have damaged interrupting equipment during normal opening operations. Furthermore, it is apparent that the circuit breaker dead time should be considered only when the circuit breaker is sufficiently open to withstand such impulses. Otherwise added interrupter arcing time may seriously reduce the interval intended for deionization.

G. Jancke (Swedish State Power Board, Kungl Vattenfallsstyrelsen, Stockholm, Sweden): The length of the dead time at automatic reclosing with regard to system stability is of great interest. The authors state that the minimum dead time is determined mainly by three factors:

1. Circuit breaker limitations. I think that we cannot neglect the spread in the relay protection time and in the electromagnetic or pneumatic-mechanical devices which govern the dead time.

2. Total duration of lightning stroke or its multiple components. The authors state that the data available at present indicate that about 10 per cent of the lightning strokes persist for more than 0.25 second. The experiences of the Swedish State Power Board refer mainly to 22-kv systems. We have statistics from 1,100 high-speed reclosures up to 1947. The system networks are grounded through Petersen coils and thus the experiences refer to 2-phase and 3-phase faults, the single-phase faults being mainly extinguished without line circuit breaker operation. Eighty-two per cent of the high-speed reclosures have been successful, while in 14 per cent of the cases a second delayed reclosure in a couple of minutes has succeeded. The fault duration has been about 0.10 second and the dead time 0.20 to 0.25 second. At first a dead time of 0.10 to 0.15 second was used but then the percentage of unsuccessful reclosures was much higher. The 14 per cent may be caused by multiple strokes, birds, trees, and so forth. On 132- and 220-kv networks we have used 0.25 to 0.30 second dead time interval with good results. Our experiences however, are not sufficient to allow any definite conclusions. In many cases it is very important to use short dead time interval with regard to stability and then we might take the risk of being unsuccessful at the relatively spare multiple strokes of long duration.

3. Deionization time of the fault-arc path and its consequent recovery of dielectric strength. The experiments made by the authors are most valuable and form a good base for the determining of the dead time interval. I am especially interested in the conclusion that high-speed relaying and fast circuit breakers are of an extreme importance. The authors promise that further tests will be performed. I think it would then be valuable to investigate single-phase reclosure and especially the influence from line section length on the minimum dead time. Furthermore many circuit breakers are fitted with resistors. On a common Swedish 220-kv circuit breaker, nonlinear resistors will be inserted to diminish switching surges. The current through the resistors will not be interrupted during the dead time. It is very small but may affect the deionization unfavorably to some extent.

E. J. Harrington and **E. C. Starr:** The comments by Mr. Umphrey relative to the influence of multiple lightning strokes on circuit breaker reclosing performance, and the experience data on high-speed reclosing in Sweden given by Mr. Jancke are valuable additions to the paper. In general, the gain in system stable capacity obtained by high-speed reclosing is very sensitive to fault and reclosure times. Fast clearing and the minimum possible dead time are highly desirable, but unsuccessful reclosures must be kept to an acceptable minimum. The present paper covers an investigation of some of the interrelated variables involved in the problem.

In reply to the excellent discussion by Mr. Browne, it should be emphasized again that the authors were attempting primarily to obtain relative information on the dielectric recovery of fault-arc paths for a limited number of fault conditions. Information was desired and obtained on the actual time required for the arc trail to deionize to such a degree as to permit full voltage to be restored across the space, using a high-impedance source to limit the current to a negligible value.

Since fault-path resistance values were available from the data obtained, and since finite currents are required to re establish such an arc, a resistance value (250,000 ohms), obtained at relatively high voltage, was chosen as a bench mark to indicate a relative state of deionization. As was stated in the paper, it is not known just what per cent of successful reclosures could be obtained at this indicated resistance; that information is yet to be obtained. The very character of the arc, that is, turbulence, looping, and path multiplicity, as vividly shown by high-speed motion pictures taken during the tests, is such as to make the minimum successful-reclosure time a matter of probability; there can be no abrupt threshold between successful and unsuccessful reclosure times.

It was pointed out in the paper that eddying of the hot gases tended to produce voids that probably resulted at times in measured resistances that would infer dielectric strengths greater than actually existed. In some of these cases the rapid rise in measuring potential caused at least partial breakdown of the voids with accompanying decrease in resistance. There is no assurance however, that reapplication of full voltage at the instant of interruption in recovery would have resulted in currents of sufficient magnitude in each case to re-establish the arc. These delays or interruptions in dielectric recovery were taken into account in the curves presented.

The equation given by Mr. Browne for arc voltage, $E_d = \sqrt{RW_0}$, is recognized as applying to stable arcs. Since the voltage drop across a given length of arc is essentially constant and independent of current, it is indicated that the critical resistance is inversely proportional to the energy loss from the path of the arc core. If that core is surrounded by a cloud of incandescent gas resulting from long arc duration at high current, the energy loss will be lower than if the gas cloud is absent or less extensive. Hence the critical resistance for arc reignition should be somewhat lower for short-duration arcs, but there is probably not an order of magnitude difference. Furthermore the short-duration arcs exhibit a much more rapid rise of resistance than the arcs of long duration. See Figures 8(A), 8(B), and 10 of the paper.

The authors cannot agree with Mr. Browne's statement that the dielectric recovery was influenced by the measuring circuit. If this were the case the extremely rapid recovery indicated in Figure 10 following a 1-cycle 15,000-ampere arc would not have occurred.

Future studies are contemplated again in connection with a limited number of circuit breaker capability and acceptance tests. Improved measuring techniques will be employed, but a source of high-voltage direct current will not be available for the measuring circuit at least not for the next tests. Some of the future work may include the influence of charging current in the arc path following fault interruption to simulate the conditions of single-pole switching.

A Transient Fault Locator for High-Voltage Transmission Lines

L. R. SPAULDING
ASSOCIATE AIEE

C. C. DIEMOND
MEMBER AIEE

THE location of high-voltage power line faults by echo-ranging means has received considerable attention during the post-war years. Recent work by the Bonneville Power Administration (BPA) in the development of high-voltage transmission line fault locators, together with a broad review of the problem in general and a rather complete bibliography, has been reported in another paper,[1] therefore, that material will not be repeated here except in brief summary. That paper describes two types of transient fault locators operating on the fault generated surge principle.

In the type *A* system, the surge from the fault travels to a station at one end of the line where it starts a timing device and reflects back toward the fault. From this instant, the device acts in normal echo-ranging sequence as though the surge were generated at the station. The round-trip time to the fault and back again is a measure of the distance to the fault.

In the type *B* system, the surge from the fault travels to a station at one end of the line where it starts a timing device. The reflection of the surge from the station bus is not used. A surge simultaneously travels from the fault to a station at the other end of the line where it is transmitted via a broad-band radio channel to the first end. The elapsed time interval between the arrival of the two surges at the first station provides a measure of the distance to the fault.

Another system also has been proposed[2] for transient fault location in which an echo-ranging type of fault locator continuously pulses the line and makes a photographic record automatically from an oscillograph during fault. This device is permanently coupled to just one phase of a 3-phase line.

Other echo-ranging fault locators of the nontransient type also have been described, or are commercially available. Most of these require that the line be removed from normal service for fault location purposes.

One type,[3] builds up direct voltage on the line to a potential high enough to break down any point of weak insulation. The surge generated by this breakdown is used to start the timing device and to reflect from the line discontinuities in typical echo-ranging sequence.

Another type,[4] requiring metallic connections to the line, applies a repetitive pulse to a permanently faulted phase of the line and gives a visual presentation of the fault location on an oscilloscope screen.

Still another type applies a continuous wave of constant frequency (nonpulsing) to a faulted phase of a line and observes the phase shift of the reflected wave.

It is the purpose of this paper to report further work by the BPA in the study of the problem and in particular to describe the type *C* fault locator which fulfills several additional requirements of an ideal fault locator.

The transient fault locator discussed in this paper permits the location of nonpermanent faults such as are often caused by lightning. These may not remove the line permanently from service, but may cause damage to insulation or conductors. It is highly important that these points of fault be located for inspection and repair.

The type *C* fault locator is designed for use where suitable wide-band communication circuits are not available to carry the intelligence requirements of the type *B* fault locator. It also provides a freedom from spurious pulses; a trace which does not require specially-trained engineering personnel for interpretation when a photographic record is used; a means of operating an electronic counter for a direct reading record; and a freedom from causing interference to closely associated carrier or radio communication facilities.

The difficulty encountered from spurious pulses associated with the surge at the start of a fault which was used as the source of pulse energy for echo-ranging in the type *A* fault locator, together with difficulty in handling the extremely wide ranges of pulse magnitudes encountered in the fault generated surge, lead to investigations of this so-called pulse-radar method of echo-ranging for fault location.

Improved methods of coupling the equipment to a live line through carrier coupling capacitors which are connected during fault by information from a conventional phase selecting relay system, were developed to obtain more pronounced reflections from the fault and a single applied pulse instead of a continuously repeating pulse was selected for simplicity and freedom from causing carrier and radio interference.

Operation of the Type *C* Fault Locator

During the waiting period between faults, the fault locator is not connected to the line. When a single-line-to-ground fault occurs, a simple phase selecting relay system connects the fault locator through a carrier coupling capacitor between the faulted phase and ground. After approximately 33 milliseconds from the

L. R. SPAULDING and C. C. DIEMOND are both with the Bonneville Power Administration, Portland, Oregon.

The authors wish to express their appreciation to A. W. Adams, H. L. King, D. E. Smith, T. T. Smith, and T. W. Stringfield for their criticisms and suggestions.

start of the fault, a single unidirectional (d-c*) 1-microsecond pulse from a 10-kv source is applied to the line after which the pulsing unit is disconnected and a receiving unit is actuated. A timing device is started by the initial pulse and the elapsed time before the return of a reflection is recorded. This provides a measure of distance to the fault. In the event of a multiple phase fault such as a phase-to-phase or 2-phase-to-ground fault suitable information from the relay system will connect the fault locator between one of the two or three faulted phases and ground.

Investigation

In the experimental work, the timing device used was a cathode-ray oscilloscope with a linear sweep. The initial pulse started the sweep and the reflected pulse appeared as another "pip" on the sweep at some time later proportional to the fault distance. The permanent record was obtained by photographing each trace on an individual frame with a standard 16-millimeter motion picture camera. This method was particularly suited to the work because of its ability to show the presence of any spurious or undesired pulses which might interfere with the operation of an electronic counter or other direct indicating devices which might be employed.

In the development of the type *C* locator, these questions had to be answered:

1. What pulse magnitude should be used?
2. What interval during the fault should be used for operating the fault locator?
3. Should the pulse be repeated continually at all times; applied on a repetitive basis during fault; or applied just once during fault?
4. What pulse width should be used?
5. Should a d-c or a radio-frequency pulse be used?
6. How should the fault locator be coupled to the line?
7. What type of recording device should be used?
8. What relaying system should be used?

Obviously these questions are all related so the best answer to one might not allow the best answer to the others.

Pulse Magnitude

In seeking an answer to the question of pulse magnitude, a large number of oscillograms were reviewed which were obtained from automatic magnetic oscillograph operations throughout the Bonneville system during a period of several years. Also, cathode-ray oscillograms obtained by photographic means during staged faults were reviewed, paying particular attention to voltage wave distortions existing during the first few cycles after the start of a fault. The information gained from the magnetic oscillograms was limited due to the comparatively low-frequency response of the oscillographs and their related inability to record steep-wave fronts of the order which would provide interference to a fault locator of the type proposed. However, it was the best accumulated source of information available and did give an idea of the frequency of occurrence of low-frequency voltage distortions in the time immediately after the start of a fault. A comparison of the magnetic and cathode-ray oscillograms indicated that it was logical to assume that indicated low-frequency distortions would be related to higher frequency distortions and that an interval free from low-frequency distortions would probably be free from higher frequency distortions. The results of this review, together with a

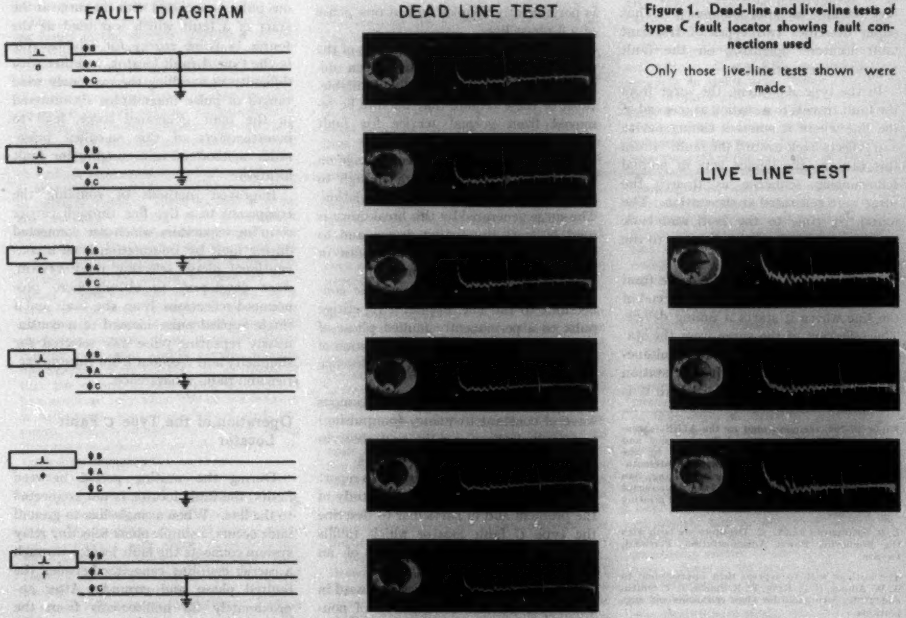

Figure 1. Dead-line and live-line tests of type C fault locator showing fault connections used

Only those live-line tests shown were made limited number of live-line fault tests using a d-c pulse for echo-ranging, disclosed that a pulse from a 10-kv source could be expected to override most interference after the second cycle of fault.

---

* The term "d-c pulse" is used to denote this unidirectional pulse.

Interval During Fault

Since the device must obtain its information before the fault is cleared, yet must wait at least two cycles of 60 cycles, the third cycle of fault was defined as the logical time for its operation.

Pulse Repetition

If a continuously repeating pulse were to be used, the time of most value in obtaining a record, for example, photographing a cathode-ray trace, would be during the third or later cycle of fault. A photograph of multiple traces on one frame might be distorted by spurious pulses if an exposure were started too soon after the start of the fault or continued through the circuit breaker opening time. The number of useful repetitions of the pulsing interval which might be expected during the third cycle of fault depends upon the length of the line being monitored and the recovery time required by the pulse originating equipment. For a 100-mile line, the theoretical maximum number of pulses could not exceed 16 and the actual practical number might not exceed five. In the event an electronic counter were employed, it could only make use of the first transmitted pulse and its reflection, so subsequent pulses would be of no value. Considering the added complications involved in delivering a repetitive pulse of the required magnitude for the benefit of the photographic record, and the questionable advantage to be gained, it was decided to use only one pulse properly placed with respect to time after fault initiation and before fault interruption.

Pulse Width and Type

In the interest of accuracy of measurement, it was desirable to use as narrow a pulse as possible. A d-c pulse of the order of one microsecond could be passed through an ordinary carrier coupling capacitor without undue losses and a d-c pulse was by far the easiest to produce. A radio-frequency pulse could be made longer than one microsecond and of any particular shape desired for easy recognition on a photographic record. However, it was felt that the reflection obtained from the type *C* locator would be pronounced enough so that a special shape of pulse would not be necessary. This fact became evident after improved coupling schemes had been developed. For the operation of the electronic counter, the magnitude of the pulse is of more importance than the shape. Therefore, the 1-microsecond d-c pulse was chosen.

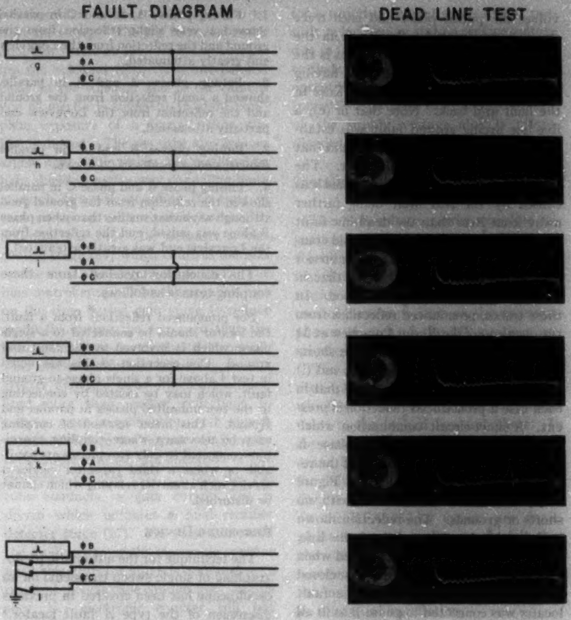

Figure 2. Dead-line tests of type C fault locator showing fault connections used

No live-line tests were made

Coupling

One of the most important factors to be decided was that of coupling to the line. Early experience with the type *A* locator[1] suggested that a loose common coupling to all phases of a station bus would not give best results for all faults regardless of the phase that was faulted. Also it suggested that close coupling to just one phase of a 3-phase line would not give equally good results for faults on the other phases.

Accordingly, a series of tests were arranged on the BPA 230-kv Ross–Longview line in which a series of connections were made at a point 32 miles from the Ross Substation representing various types of faults but with the line dead. Phase B was pulsed through the coupling capacitor at Ross Substation for each condition. In order to verify the assumption that these dead-line connections would appear practically the same to the fault locator as an actual fault, three of the combinations were repeated under arcing line to ground fault conditions. The results of these tests are summarized in Figures 1 and 2. Phasing shown in Figures 1 and 2 is that existing at the point of fault.

In these figures, the left-hand columns show the fault connections for each test. The square attached to the top phase represents the fault locator. The center column shows the photographic record made for each dead-line test. The right-hand column shows the record made for an actual arcing line to ground fault for the condition shown in the left-hand column. In these cases, the fault was produced by pulling a small copper wire into the line with a glass string. The traces shown have been touched up for reproduction purposes by inking over various reflection "pips". The regularly spaced negative "pips" appearing on each trace are range markers indicating each ten miles of line.

Figure 1 shows 3-phase, 2-phase, and single-phase grounds designated as A, B, and C respectively. Each case involves the pulsed phase and each trace shows a pronounced reflection from the ground. The reflection at 64 miles is the second return of the pulse after having completed two round trips from Ross to the fault and back. Note that in (c), a live-line arcing ground fault was established for purposes of comparison and that the two traces check each other. The slight difference in distance indicated was caused by the real fault being farther away from Ross than the dead-line fault connection. Figure 1 shows ground combinations at (d), (e), and (f) which do not involve the pulsed phase. Note that in each case the reflection is not good. In these traces, pronounced reflections from the open end of the line at Longview at 51 miles are present. Figure 2 shows short-circuited combinations at (g), (h), and (i) involving the pulsed phase. Note that in each case a pronounced reflection is present. A short-circuit combination which does not involve the pulsed phase is shown by Figure 2 (j). Note that the reflection from the fault is not good. Figure 2 (k) shows a trace obtained with no shorts or grounds. The reflection shown is from the Longview end of the line. Figure 2 (l) shows a trace obtained when the ground switch at Ross was closed grounding all three phases. The fault locator was connected to phase B as in all the previous tests through a carrier coupling capacitor on the line side of the carrier line traps about 50 feet away from the ground switch. Note that the different shape of the reflection from the Longview end at 51 miles consists of high-frequency oscillations apparently caused by the line connections at Ross.

The fact that every reflection shown extends both above and below the base line indicates that even though the pulse originates as a unidirectional pulse, its characteristics are modified by the system parameters and connection of the circuits through which it feeds and to which it is connected. This might suggest that a radio-frequency pulse would be affected by these reactances and that for greater efficiency, it is desirable to shock-excite these reactances with a d-c pulse.

Additional dead-line tests were made with a ground on B phase 32 miles from Ross, but with the fault locator coupled through carrier coupling capacitors to various combinations of paralleled phases. All parallel connections were made on the fault locator side of the coupling capacitors.

Photographic records of these tests are not reproduced in this paper but the results are as follows:

1. Pulsing phases A, B, and C in parallel showed a very slight reflection from the ground and the reflection from the Longview end greatly attenuated.
2. Pulsing phases A and B in parallel showed a small reflection from the ground and the reflection from the Longview end partially attenuated.
3. Pulsing phases B and C in parallel showed similar results to (2) above.
4. Pulsing phase A and phase C in parallel showed the reflection from the ground good although somewhat smaller than when phase B alone was pulsed, and the reflection from the Longview end was greatly attenuated.

The conclusion reached from these coupling tests is as follows:

> For pronounced reflections from a fault, the locator should be connected to a single phase which is involved in the fault and ground. One exception to this was noted in test 4 above for a single-phase-to-ground fault, which may be located by connecting to the two unfaulted phases in parallel and ground. This latter method of coupling may be necessary where coupling capacitors connected to only two phases are available or where a third capacitor carries a service such as carrier relaying which cannot be disturbed.

RECORDING DEVICE

The technique for the automatic photographing of single sweep transients on an oscilloscope has been covered in previous discussion of the type *A* fault locator.[1] Until the satisfactory operation of an electronic counter as applied to the type *C* locator has been fully confirmed by experience, the use of the oscilloscope and camera will be continued. An electronic counter now on order will later be incorporated in a type *C* fault locator now being constructed for installation at Spokane Substation, together with the oscilloscope photographic recording equipment. In this way, the oscilloscope trace can be used to check the operation of the counter and it is hoped that the photographic recording equipment can eventually be eliminated.

In operation, the initial pulse will start the counter which records the number of 1-microsecond time intervals until it is stopped by a reflected pulse from the fault. The reading appears on a decade bank of lights which hold their indication until manually reset. The time necessary for the pulse to travel one mile and to be reflected back to the point of origination is 10.73 microseconds. The fault distance in miles will be obtained by referring the indicated time interval to a calibrating curve.

RELAYING SYSTEM

Various means for controlling the time of pulse application were considered for the type *C* fault locator. Economy of equipment dictated use of a relaying scheme which would switch the fault locator to one of the faulted phases on either line. Employing relatively inexpensive relaying components allows the use of the more complex and expensive electronic devices in this equipment, such as the oscilloscope, for fault location on more than one 230-kv line.

Limitations of available electro-magnetic relays including inertia, burden, and so forth, should not present too many problems in this application. However, we are hopeful that newer developments possibly in electronic relays will permit closer control of this fault locator.

FUNCTIONAL DETAILS OF THE TYPE *C* FAULT LOCATOR

The functional details of the type *C* fault locator are shown diagrammatically in Figure 3. In this figure are shown a transmission line (1) connecting two substation busses, a fault (2), carrier current coupling capacitors (3) for each phase and coupling capacitor selector relay contacts (4) which are operated by the phase selecting relay system. The connections leading to a typical carrier communication equipment (5) and a conventional protective gap (6) for protection of the line tuning unit are also shown.

When a C-phase-to-ground fault occurs, the phase-C selecting relay operates the related coupling capacitor selector relay so as to first disconnect the carrier communication equipment and second, to connect the fault locator to this phase. Simultaneously, the pulse originating relay which operated contacts (7) is energized. This relay, together with the phase selecting relay, is timed to operate from 2 to $2^1/_2$ cycles after the start of a fault. The coupling capacitor selector relay contacts are timed so as to always close ahead of the pulse originating relay contacts (7). As these pulse originating relay contacts move towards closure, the voltage from the 10-kv power supply breaks down gap (8) and the reduced gap across contacts (7), applying a pulse through the phase C coupling capacitor to the line. Due to the constants of the coupling capacitor, the line, and the supply circuits, current will flow through the coupling capacitor for a time in the order of one microsecond. This completes the transmission of the pulse.

As long as the arc across gap (8) continues, the relatively large output capacitor (9) in the 10-kv power supply provides a shunt path to ground through which any reflection coming back to the station will pass. In order to disconnect this part of the circuit as quickly as possible after the pulse has been originated, an 8-ohm resistor (11) and gap (12) were provided through which the output capacitor will discharge in about ten microseconds. This gap (12) shorts out the 750-ohm resistor (13) during the discharge of the output capacitor so as to reduce the voltage fed to the receiving circuit through coupling condenser (14).

The phase selecting relay system in the fault locator is arranged so that all elements reset when the fault current is cleared. After gap (8) has fired, condenser (9) has discharged, and the arc across gap (8) extinguished, the voltage across condenser (9) is prevented from building up to full value immediately by resistor (33). This gives the pulse originating relay contacts time to reset before gap (8) would break down a second time. In this way, only one pulse is supplied to the line for each fault.

Gaps (12) and (8) extinguish simultaneously leaving the receiving circuit connected to the line through the 8-ohm resistor (11). The 750-ohm resistor (13) provides little shunting effect to the desired incoming signal yet assists in properly terminating the line from the carrier capacitor. Coupling condenser (14) together with coaxial cable (15) acts as a differentiating circuit to discriminate against low-frequency signal components attempting to enter the receiving circuit. The high-pass filter (16) provides proper termination for the coaxial cable and discriminates against all frequencies below 200 kc, in particular the carrier frequencies. In this way, even though the carrier transmitter connected to the line is operating at the time of fault, it will not interfere with the operation of the fault locator through stray coupling which inevitably exists around the coupling capacitor selector relay contacts. The carrier signal is interrupted only during the fault and is restored to normal as soon as the circuit breaker is opened and the relays reset. On a voice circuit, this provides very little more interference than the fault itself together with fault interruption by the circuit breaker.

A limiter amplifier (17) is provided in the receiving circuit which prevents the initial pulse from distorting the trace (in the case where an oscilloscope is used) or from saturating one of the following stages.

Breakdown of gap (8) also results in application of a positive pulse to the grid of a gas tube (18) through coupling condenser (19) and coaxial (20). This causes the gas tube to conduct and to supply a positive pulse to the oscilloscope (29) to start the sweep. The gas tube also racks up a new frame on the camera by operating the solenoid (22). The mechanical delay in the solenoid and in the camera due to inertia is sufficient to allow complete exposure of a frame before the film is moved. The gas tube also fires an argon light (23) within the oscilloscope light shield in such a way as to illuminate a watch face for recording the time of each sweep on each exposed frame. In addition, gas tube (18) actuates a bias control stage (24) which controls the bias on the time varied gain stage (25). The bias control stage allows the negative bias on the time varied gain stage to reduce gradually during the sweep so that the gain will increase during the sweep period. This allows reflections returning from a greater distance away which are attenuated more than earlier reflections to receive more amplification and appear more uniform on the record. Uniformity is desirable also for the operation of the electronic counter (31). When the gas tube conducts, a gate circuit (26) is driven which actuates a final rectifier detector stage (27). No pulse can reach the oscilloscope or the electronic counter until this detector stage is actuated as a result of the gas tube conducting. In this way, the electronic counter will not operate at the wrong time due to spurious pulses feeding into the receiving circuit across the capacitance of coupling capacitor selector relay contacts or through other stray coupling. The d-c plate voltage is removed momentarily by reset circuit (28) after completion of one chain of operation.

The camera (32) is a standard 16-millimeter motion picture camera with the shutter removed. Each frame is continually exposed to the oscilloscope screen but the screen is completely blanked out between operations.

Difficulty was experienced at first from light radiation from the cathode of the cathode-ray tube coming directly through the screen into the camera and clouding the film. After attempts were made to correct the trouble with light filters, this undesirable condition was finally overcome by lowering the camera several inches so that it was out of the direct line from the cathode. In order to prevent small quantities of stray light from eventually clouding the film, the camera is racked up automatically once an hour by a pair of contacts which are operated by a clock motor.

It is desirable in automatic models to use large storage condensers throughout the equipment to sustain the d-c voltages for a period of several cycles during possible reductions in station service voltage due to fault. Use of electron tubes of the cathode type which maintain satisfactory operating temperatures for several cycles (on a 60-cycle basis) after an interruption of the supply voltage also is recommended.

Installation at Spokane Substation

The high-voltage carrier coupling capacitors required for operation of the type *C* locator is a major item of expense. The installation of the device at Spokane Substation has been simplified by the presence of these capacitors on the necessary phases of each of the 230-kv lines terminated there.

The scheme as designed for Spokane uses phase selecting relay equipment which switches the fault locator equipment to the faulted line and phase. In the actual installation as shown in Figures 4 and 5, selecting equipment is provided for only the line-to-ground faults. Since the overwhelming preponderance of faults on the BPA 230-kv system are single-phase-to-ground faults, it was felt that the added complication necessary to recognize and properly switch the locator for multiphase faults was not warranted in this initial installation.

The phase selector relays are high-speed directional elements. In this application, the faulted phase is selected by comparing the direction of power transformer neutral current with phase current. The faulted line is determined by operation of an instantaneous overcurrent relay or by the operation of a directional comparison carrier ground auxiliary relay. The overcurrent relay is set above the maximum through fault current for each line.

Operating experience in this particular application may show the need for a more complex phase selecting scheme. If changes are found necessary, it is planned to use a negative-zero sequence current comparison scheme as in a previously reported system for single pole reclosing.[6]

A modification of the basic relaying scheme is shown for Spokane at the bottom of Figure 5. Here the coupling capacitor on phase A of each line carries the carrier relaying channel. On this channel, the carrier signal cannot be interrupted during fault as can voice channels. In order to avoid filtering the fault locator pulse out of the carrier relay equipment which would be connected in parallel during the fault locator operating period, it was decided to try the connec-

tion scheme indicated by test (4) in the section on coupling in which phases B and C are paralleled and pulsed for faults occurring on phase A.

A separate pulsing unit for each of the two 230-kv lines is provided for Spokane, one mounted on each dead end tower. Each unit includes a 10-kv power supply, a pulse originating relay and the associated gaps, three coupling capacitor selector relays, and coaxial fittings for terminating two coaxial cables connecting to the receiving equipment. The corresponding coaxials from these two pulsing units are connected in parallel so that only one receiving unit is required.

In addition to its primary function, the location of power line faults, it is felt that this equipment might prove to be a valuable tool in investigation of phenomena related to traveling waves and line attenuation on high-voltage transmission circuits. We also can see some possibilities for power line relaying with related devices. It also has been suggested that a continuously pulsing device of this kind using a high repetition rate might be used in the investigation of fault arc deionization time and lightning discharge duration.

At the present date, we have made no detailed analysis of the data so far obtained on the BPA system on traveling waves and line attenuation.

Discussion

Y. J. Fujimura (Department of Water and Power, Los Angeles, Calif.): With the ever-increasing installation of high-voltage transmission lines of considerable length, often through territories not easily accessible, the necessity and the value of an improved method for quickly locating transient faults become apparent. The engineers of the Bonneville Power Administration have contributed a great deal toward the ultimate goal of an ideal fault locator[1] and this paper is welcomed as another step forward with possibilities of approaching the ideal requirements.

The Los Angeles Department of Water and Power is interested in some quick means of determining the location of transient faults which may occur on the 250-mile 230-kv Owens Gorge line to be constructed in the near future. Basically, we have considered schemes which depended upon one of the three sources of possible fault indication; by measurement of the fault current, by timing the traveling waves impressed on the line from an external source, and by timing the surge generated by the fault. None of the various schemes in its present state satisfies all the requirements of an ideal fault locator.

The paper indicates that this new method called type *C* is still in the experimental stage. Its two outstanding features are a new improved means of coupling to a live line and the possibility of obtaining records without the use of photographic films. We hope that they will succeed in developing an electronic counter and its auxiliaries which will operate only on the desired pulses. An electronic counter will eliminate film development and the necessity of skilled interpretation, and it will give more accurate indication with respect to distance.

What would happen if the lines were hit by a multiple lightning stroke? There is the possibility that subsequent strokes will generate surges which may interfere with the reflected pulse. It is true that the initial fault surge will have practically disappeared by waiting two cycles, but a lightning stroke may contribute surges which may occur several cycles after the initial stroke. If the authors can separate the reflected d-c pulse from any other pulses by some filter arrangement, the objection to interference will be eliminated.

Their experimental data from tests on the Bonneville Power Administration 230-kv Ross-Longview line are based only on solid faults on dead lines and on arcing faults on live lines. Appreciable reflection resulted by proper coupling to the faulted phases; however, on other types of faults involving high resistance to ground or between phases, the reflection may be too small to be identified on the scope or to operate the electronic counter.

Type *C* method also is limited to faults located more than a mile beyond the point of application of the d-c pulse. As the authors indicate, some ten microseconds are required for the output capacitor to discharge, which will block out the receiver for that period. Possibly a time delay circuit may overcome this difficulty.

1. A TRANSMISSION LINE FAULT LOCATOR USING FAULT-GENERATED SURGES. **R. F. Stevens, T. W. Stringfield.** *AIEE Transactions*, volume 67, part II, 1948, pages 1168–79.

J. R. Leslie and **K. H. Kidd** (The Hydro-Electric Power Commission of Ontario, Toronto, Ontario, Canada): The pulse technique of fault location on power and telephone lines is receiving a great deal of attention and several groups are pioneering in the development of various instruments which operate on the same basic principle but which differ in detail. The Bonneville Power Administration is to be commended for the thorough manner in which it is investigating several of the possible methods.

The echo-ranging fault locator, utilizing a repetitive short duration d-c pulse, has become well established as an instrument for locating sustained faults.

The Hydro-Electric Power Commission of Ontario now has seven of these instruments located at strategic points in its operating area. These have been used with great success on a wide variety of telephone circuit faults. Operating experience on power lines has been limited, but the instruments have been of use in phasing in new circuits, checking for construction grounds, and in detecting faulty openers. Tests indicate that a variety of faults may be detected including phase-to-phase, phase-to-tower and phase-to-sky-wire short circuits, on open circuited phase conductors, and a phase conductor lying on or near the ground.

The Hydro-Electric Power Commission of Ontario also has in operation an experimental transient fault locator which is similar in principle to that described by Spaulding and Diemond but which differs in a number of details. The authors use a single short duration d-c pulse of about one microsecond duration, whereas The Hydro-Electric Power Commission has been experimenting with a short duration burst lasting about 40 microseconds and containing about ten cycles at a frequency of 250 kc per second. There are theoretical advantages to be claimed for either method and the choice must finally rest on actual operating experience. It is fortunate that the two techniques are being tried simultaneously under roughly similar circumstances, so that their relative merits should be clarified in the near future.

The short duration d-c pulse may be generated more simply than the wave burst and a large amplitude can be obtained much more readily. The wave burst equipment at present produces a voltage of about 500 volts peak to peak as compared to 10 kv utilized by Spaulding and Diemond, a ratio of about 26 decibels. A 1-microsecond pulse also is desirable in preference to a 40-microsecond pulse, in that the accuracy of distance determination is improved accordingly.

The d-c pulse has a much sharper front than has the burst and this is a desirable factor in that it produces a larger reflection from certain types of faults. Thus, a sharp fronted pulse is essential in the sustained fault locator in order to detect a phase conductor lying on high resistivity ground. However, in the case of an arcing fault on an energized line either shape is probably equally acceptable in this respect.

The attenuation along the line is greater for the shorter duration d-c pulse and it also may be more difficult to detect it in the presence of background noise. It is doubtful whether a 200-mile range can be attained with such a short duration pulse.

The main factor which may favor the burst is that the burst energy is confined to a narrower frequency spectrum than that of the d-c pulse. It is very desirable that the transient fault locator be operated without interference to or from carrier equipment on the same transmission line and possibly on the same coupling capacitor. Interference to the carrier receiver is not a problem since both the d-c pulse and wave burst are of such short duration. However, the carrier transmitter may interfere with the fault locator receiver particularly when they use the same capacitor. The present wave burst receiver utilizes a bandpass filter with a pass band of 100 kc centered on 250 kc and an attenuation peaking to 60 decibels at the carrier frequency of 172 kc and also rising to 30 decibels through the broadcast band. Careful attention must be paid to the transient response of the filter to assure short rise time and freedom from ringing.

Of course the simpler approach might be to shut off the carrier equipment for several milliseconds while the pulse is transmitted but it is feared that this would restrict the versatility of the instrument.

The two instruments also differ in a number of minor details. Spaulding and Diemond use a single pulse whereas The Hydro-Electric Power Commission uses a repetitive burst, sending out from five to eight bursts for a transient fault. The first method again gives simplicity and economy of equipment while the latter may be expected to give a clearer photographic record particularly in the presence of noise. The Hydro-Electric Power Commission equipment is used for observing sustained faults visually as well as transient faults photographically and hence the repetitive burst is necessary.

Both groups use a photographic recording technique at present and they appear to be equally anxious to get away from it. The electronic counter will be a most desirable advance but much experience will be needed before a suitable sensitivity is chosen. In some cases, it also may be necessary to render the counter insensitive to large fixed echoes from stations or junctions along the circuit under test.

The Hydro-Electric Power Commission group feel that the photographic technique is satisfactory so far as the operator's ability to interpret the record is concerned, especially as a photograph of the normal appearance of the circuit also is provided him. However, the time and trouble of processing the film is undesirable. Some thought is being given to magnetic tape or smoked chart recording, but the required writing speed may be too high. A magnetic tape record which the operator could play back onto the cathode-ray tube seems inviting.

L. R. Spaulding: In answer to Mr. Fujimura's first question, it is true that a lightning stroke, subsequent to the first one, which started a power arc might fall during the interval of operation of the type *C* fault locator and could cause interference. It would be more difficult to overcome this interference by use of a filter in this sytem than for a system using a radio-frequency or waveburst pulse. This is one thing in favor of the waveburst pulse.

Regarding high resistance faults, it does not appear likely that a high resistance fault will occur under transient or live line conditions on a 230-kv line. As a transient fault locator, the device depends upon a power arc for the reflecting discontinuity, and requires fault currents to accomplish the necessary relaying functions.

If a line fails to go back into service after an outage, a permanent fault may be located on the dead line by manually operating test switches provided for individual phase selection and pulsing. High resistance faults may be located either phase-to-ground or phase-to-phase by this means. The short duration d-c pulse is better for this purpose than a low frequency wave burst pulse.

As noted, the fault locator will not indicate faults in the first mile of line due to the time required to de-energize the transmitter and actuate the receiver. This is considered one of the limitations of the device. However, usually there are other visual indications for faults this close to a station. It was felt that the added complications necessary to overcome this deficiency were not warranted.

The comparison by Mr. Leslie and Mr. Kidd of the advantages and disadvantages of a d-c pulse versus a wave burst for echo ranging describes one difference between the Linascope and the type *C* fault locator. However, the greatest difference in the type *C* is in the use of a phase selecting relay system to connect the fault locator to the faulted phase. This results in a greatly increased reflection from the fault. It also provides a means of monitoring all phases on several lines with one set of equipment. When one conductor of a 3-phase line is pulsed and another conductor is involved in a fault, our tests show that the reflection from the point of fault is apt to be small or unusable, depending upon type of fault and the balance of the line constants.

In the discussion closure of Leslie and Kidds' paper,[1] they have indicated that their transient Linascope is connected to one phase only of a 220-kv bus through which four lines are paralleled. We believe our use of phase-selecting relays to be a distinct improvement in coupling means.

We recognize that the attenuation along the line is greater for a short duration d-c pulse than for a wave burst. However, the maximum line length to which it will be applied is about 136 miles. We do not plan to monitor more than one line section with the device, that is, station-to-station. It is at present temporarily installed at Spokane on the two 230-kv lines between Coulee and Spokane. Their lengths are 83 miles each. Very satisfactory reflections from the far end of these lines is obtained.

We have noted with interest certain advantages reported in favor of a radio-frequency, or wave burst pulse. Should our operating experience indicate the need, we shall give further consideration to this type of pulse.

Electrical Design Features—Steam-Electric Generating Station P of the Pacific Gas and Electric Company

FRANCIS S. BENSON
MEMBER AIEE

A STEAM-ELECTRIC generating station known as Station P (Hunters Point) is located on the west shore of San Francisco Bay within the city of San Francisco, Calif. The original plant was completed during 1930, the installation consisting of one 35,000-kw 12-kv 3-phase 60-cycle condensing turbogenerator and a 3,500-kw turbogenerator (noncondensing and spinning type) for supplying power to the station auxiliary motors. The main generator supplied energy to an outdoor 12-kv bus from which feeders radiated to load areas.

The extension of Station P, completed during the spring of 1949, consists of the installation of two 100,000-kw 0.87-power-factor 13.8-kv condensing turbogenerators, and two 7,500-kw 0.7-power factor 4.16-kv condensing spinning turbogenerators installed in an extension of the turbine room. The new 100,000-kw generators supply electric energy at 13.8 kv to single-phase step-up transformers, the high-voltage terminals of which are directly connected to the 115-kv outdoor ring bus.

The electric energy leaves the 115-kv bus over three underground high-voltage pipe-type high-pressure nitrogen-gas-filled cables, each cable having a rating of 100,000 kva at 120 kv. The insulated conductors in the pipe are maintained at a pressure of 200 pounds per square inch. Two pipe-type cables transmit energy to Station H (Martin Station), and one cable supplies energy to Mission Substation, located in the downtown area of San Francisco.

The terminal position of each high-voltage underground cable at Station P is equipped with a grounding switch, in addition to the usual circuit disconnecting switch. This grounding switch is used to drain the capacitance charge off the cable after it has been disconnected from any source of energy.

115-Kv Ring Bus

The high-voltage (115-kv) ring bus is built outdoors; it consists of a number of steel structures equipped with insulators, disconnecting switches, and oil circuit breakers. Figure 1 is a single-line diagram of the ring bus. Each oil circuit breaker has a current rating of 1,200 amperes at 115 kv and an interrupting rating of 3,500,000 kva. Each circuit breaker also is equipped with six multitap bushing current transformers and two or four capacitor-type potential devices. No 115-kv potential transformers are used.

The ring bus is supplied with energy from two main transformer banks, each having a capacity of 111,750 kva and each consisting of three 37,250-kva 13.8/115-kv single-phase transformers which are outdoor, forced-air rated. The transformer banks are connected delta-Y, and the high-voltage winding neutral is solidly grounded. The transformer installation is equipped with transfer disconnecting switches on both the high- and low-voltage sides for electrically connecting a spare single-phase transformer in the position of any other transformer.

One 50,000 kva 3-phase transformer with $7^1/_2$ per cent plus or minus tap-changing-under-load equipment is installed to interchange energy between the 110-kv and 12-kv systems. This is an outdoor forced-air-cooled transformer rated 110/12 kv, connected Y-Y with a tertiary winding connected in delta.

Main 13.8-Kv Generators

The main generators are a single-winding type; they are hydrogen cooled, having a rating of 115,000 kva at 15 pounds per square inch hydrogen. Full-rated current is 4,820 amperes at 13,800 volts. Automatic voltage regulation is provided using amplidyne voltage regulators for each generator. The field voltage is 250 direct volts, supplied by a 1,200-rpm 450-horsepower motor-driven exciter of 300-kw capacity, direct connected to a 7.5-kw amplidyne pilot exciter. including regulator is provided for the generators in case one of the generator motor exciters is out of service. Each exciter unit is equipped with a flywheel to maintain full exciter output for a short period of time if motor power fails. The voltage regulation system is designed for an excitation response of 0.5.

The terminals of the main generators are connected to the step-up transformers through a 13.8-kv 5,000-ampere isolated-phase bus, enclosed in metal ducts. A 5,000-ampere air-blast circuit breaker having an interrupting duty of 2,500,000 kva is installed in the 13.8-kv bus between the step-up transformer bank and the generator terminals. A single-line diagram, Figure 2, shows the main station electric connections. A 10,000-kva station auxiliary power transformer bank is connected to the 13.8-kv bus through a 2,000-ampere air-blast circuit breaker having an interrupting rating of 1,500,000 kva. These circuit breakers operate with an air pressure of 250 pounds per square inch. The 13.8-kv bus connections are such that the station auxiliary power transformers may receive power from the 115-kv bus when the main generator is out of service.

The neutral point of each main generator winding is grounded by elevated neutral equipment consisting of a 50-kva 7,620–120/240-volt single-phase transformer, the 240-volt secondary winding of which is shunted with a 50-kw resistor. An alarm relay and a double-scale voltmeter, one scale indicating 1/10 the value of the other scale, are connected across the 120-volt coil of the transformer secondary.

4,160-Volt Auxiliary Station Power System

The 4,160-volt auxiliary station power supply is made up of two ring busses connected together by circuit breakers. Refer to Figure 3 for the single-line diagram of connections. One 7,500-kw house turbine and one 10,000-kva house bank is connected to each ring bus. Each ring bus is operated normally as a separate auxiliary power system, but the busses may be connected together for emergency operation. The house generator and the house bank each have sufficient capacity to supply the auxiliary power load connected to each ring bus section; one acts as a standby source of power to the other. The house turbines have a rating of 7,500 kw, 0.7 power factor, 10,714 kva, 4,160 volt, three phase, 60 cycles; each house bank has a rating of 10,000 kva, 13.8/4.16 kv, three phase, self-cooled and 13.333 kva, forced-air-cooled; the windings are connected delta-delta. The transformers are single-phase units; their high-voltage and low-voltage terminal connections are arranged with metal links to allow any two single-phase transformers to be quickly reconnected as an open-delta bank having a capacity of 7,600 kva, three phase, forced-air-cooled.

Each house generator has automatic voltage regulation and is equipped with a shaft exciter and pilot exciter, using 250 direct volts as a field voltage. The excitation system has a voltage response of 0.5. A 2,000-ampere 5-per cent metal-enclosed 5-kv indoor current limiting reactor is installed in the house generator lead to the ring bus to reduce the possible short-circuit current on each ring bus.

The 4,160-volt ring bus is made up of 5-kv metal-enclosed lift-up-type electrically-operated air circuit breakers, mounted in steel cells. The circuit breakers have a rating of 1,200 amperes for motors and 480-volt transformers, and 2,000 amperes for the house generators, house transformers, and bus section circuit breakers. They have an interrupting duty of 250,000 kva at 5.0 kv.

The ring busses are connected together through two bus section circuit breakers in series. A connection to the spare exciter motor is taken off the center posi-

tion between two bus section circuit breakers, while a connection to boiler feed pump number 5 is taken off the center connection between the other two bus section circuit breakers. Figure 3 indicates this connection.

The following station auxiliary power load is supplied from the 4,160-volt busses:

Four 1,000-kva 3-phase oil-immersed self-cooled 4,160/480-volt transformer banks.

Four 400-horsepower circulating-pump motors (Main generating units).

Three 300-horsepower auxiliary salt-water pump motors (Auxiliary cooling service).

Four 2,000-horsepower boiler fan motors (One per boiler).

Five 2,000-horsepower boiler feed-pump motors.

Three 450-horsepower motor-driven exciters.

The small motors, 300, 400, and 450 horsepower, are started across the line at full voltage. The 2,000-horsepower motors are equipped with starting reactors and a starting circuit breaker connected in the neutral leads of the motor; six leads are brought out of the motor enclosure. These motors start at a reduced line voltage of 50 per cent.

The 4,160-volt auxiliary power supply is delta-connected; however, the house generator windings are Y-connected. The neutral point of the generators is grounded through an elevated neutral connection consisting of a 10-kva 2,400-120/240-volt distribution transformer having a 10-kw resistor connected across the 240-volt secondary winding. A double-scale voltmeter and an alarm relay are connected to the 120-volt coil of the transformer secondary winding.

480-Volt Auxiliary Power System

The 480-volt auxiliary power system is made up of 12 load centers placed at centers of motor concentrations about the plant; they are connected to each other by tie cables. The load centers are supplied with energy from four 1,000-kva 3-phase oil-immersed self-cooled 4,160/480-volt delta-connected transformers. This auxiliary power system consists of load centers which are interconnected as a sectionalized radial system. Each load center is metal enclosed, and is equipped with drawout circuit breakers; each load center bus is sectionalized into two or three sections connected together by bus-section circuit breakers. All air circuit breakers are 3-pole, electrically operated, equipped with thermomagnetic overcurrent protection; they have an interrupting rating of 25,000 amperes for motor and lighting transformer circuits and 50,000 amperes for main load-center tie circuits and bus-section circuit breakers.

Motors

All motors in sizes from 1 to 200 horsepower are 480 volts, and are splash-proof or drip-proof when installed indoors. Motors installed outdoors are totally enclosed, fan-cooled. Machine-shop motors only are the conventional open type. All 480-volt induction motors are full-voltage line-start type. All motor windings are required to have boiler-room or powerhouse treatment.

The 2,000-horsepower 4,160-volt 3-phase motors are totally enclosed, equipped with built-in water-to-air heat exchangers, which are mounted on top of the motor. A moisture detector relay is installed in each motor to indicate excessive moisture within the enclosure, which may be caused by a small leak in the heat exchanger tubes. These motors are equipped with starting reactors and starting circuit breakers connected in the neutral leads.

All motors are induction type, except the fuel-oil pump motors which are wound-rotor type, and are equipped with resistors to give full pump output at three speeds: 1,530, 900, and 450 rpm.

Lighting

Lighting circuits are 3-phase 4-wire supplied with energy from 3-phase indoor dry-type transformers, rated at 25 kva and $37^1/_2$ kva, and are connected 480-120/208 volts, delta-Y. The neutral point of the secondary winding of the transformers is solidly grounded. All lighting circuits are connected between phase wires and neutral; they are pro-

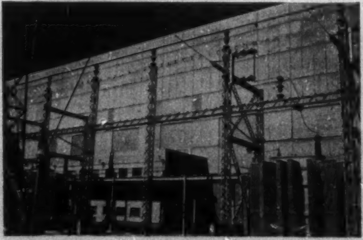

Figure 7 (left). 13.8 / 115 - kv step-up transformer arrangement

Figure 9 (right). Central control room arrangement

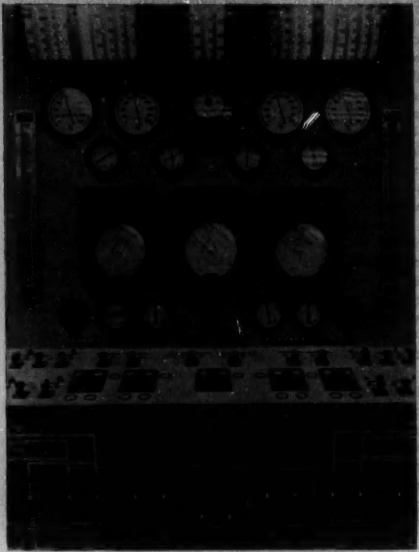

Figure 10. Master control board

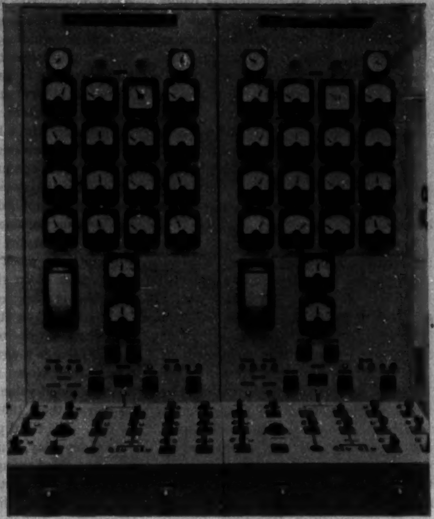

Figure 11. Main generator control panels

tected by single-pole 250-volt a-c thermal circuit breakers. The lighting neutral is carried throughout the plant as an insulated conductor.

The switchboard control room and offices are lighted with surface-mounted fluorescent lighting units enclosed in prismatic glass fixtures, which project some light against the ceiling, eliminating a marked lighting contrast between walls and ceiling. All other lights within the plant area are Mazda lights mounted in prismatic glass fixtures.

An emergency d-c lighting system is installed; certain lighting circuits normally operating on alternating current and using Mazda lamps are switched automatically over to the 125-volt d-c battery system, in case the a-c power supply fails, by double-pole double-throw electrically-operated industrial type contactors. These circuits are returned automatically to the a-c power supply when a-c voltage returns to normal. Small motors, less than 1-horsepower single-phase and 3-phase, are connected to the 208-volt 3-phase power supply.

125-Volt D-C Battery and Control Service

The 125-volt d-c control power system is supplied with power from a 60-cell 640-ampere-hour (8-hour rate) chloride accumulator type storage battery. Two motor-generator battery charging sets are installed; each generator is a diverter pole type with 25-kw capacity, two wire, whose maximum ceiling voltage is 140 direct volts.

The 125-volt d-c switchgear is metal enclosed with sectionalized busses for the control circuits so that all control power is not lost if one bus fails. The battery and charging-set bus connections are such that either battery-charging motor-generator set can be used to trickle charge or gas the battery, while the other set is connected to the control bus.

All 125-volt d-c circuits are protected with thermal circuit breakers or fuses of proper rating. Refer to Figure 4.

Circuit and Equipment Protective Relays

A modern steam plant requires many auxiliary relays in addition to those used for circuit and equipment protection. Each of the three main 110-kv underground cable circuits is protected by three high-speed directional overcurrent relays, one high-speed directional overcurrent ground relay, and pilot carrier-current ground relays.

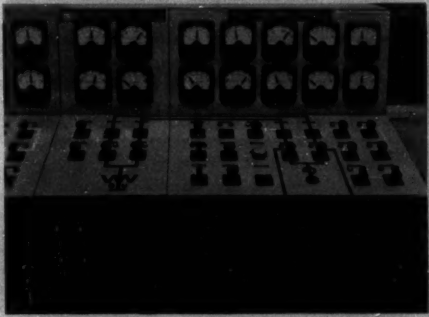

Figure 12. House generator and house transformer board

The main step-up transformer banks, 13.8/115-kv (121,750 kva) are protected with differential relays (10-cycle type) and 4- to 15-ampere overcurrent standard time, inverse relays for back-up protection. The 115/12-kv step-down 3-phase transformer bank (50,000 kva) is protected by differential relays and 4- to 15-ampere overcurrent standard-time inverse relays. The 115-kv outdoor bus is a ring bus; the 115-kv cable and transformer bank protection overlap each other.

The main generators are protected by differential relays (1-cycle type).

The house transformers are protected by differential relays (10-cycle) and 4- to 15-ampere overcurrent standard-time inverse relays for back-up protection. The house generator is protected by differential relays (1-cycle type).

The 4,160-volt ring bus is protected by two sets of bus differential relays, one set for each half of the ring bus overlapping the other; therefore only 1/2 of the ring bus will be lost if a short circuit occurs on the other half of the ring bus. All 4.16-kv motors are protected with 2- to 8-ampere overcurrent long-time inverse relays, and equipped with instantaneous overcurrent elements having a rating of 20 to 80 amperes.

If the 4,160-volt motor protection fails and a short circuit is maintained on the motor feeder because its circuit breaker fails mechanically, certain overcurrent relays (4 to 15 amperes), acting as short-circuit current relays, will close their contacts and trip the house bank, 4.16-kv circuit breakers and one generator circuit breaker supplying power to that half of the ring bus which is in trouble. The other generator circuit breaker remains closed. Therefore, only 1/2 of one ring bus is de-energized when a circuit breaker fails to open due to mechanical trouble.

During normal operation, the 4.16-kv house transformer bank and house generator operate in parallel with the high-voltage (115-kv) transmission system. In case of severe transmission system disturbances, the 4.16-kv auxiliary power bus will be separated from the main 115-kv system and operate as a separate power supply for the station auxiliaries, which then will be supplied with electric energy by the house turbines. The auxiliary bus separates from the transmission system automatically when one of three protective relays close their contacts. The first relay is a frequency relay, adjustable type, set to close its contacts when the frequency drops to 58 cycles. The second relay is a directional over-current type, which closes its contacts when a predetermined value of kilovolts-amperes flows from the 4,160-volt bus to the 13.8-kv bus. The third protective relay is an out-of-step relay, which closes its contacts after the third swing during system disturbances; the function of each relay is to separate the auxiliary bus from the transmission system during abnormal disturbances.

Fire Protection

A modern generating plant requires fire-fighting equipment especially adapted to the fire hazards at hand. In general, the plant fire protection equipment consists of four separate forms of suppression equipment; they are: fixed CO_2 gas, mechanical foam equipment, a standby hydrant and hose system using fixed fog nozzles, and portable first-aid fire equipment.

The portable first-aid equipment consists of 1-quart and 1-gallon carbon tetrachloride extinguishers, stored-pressure type using nitrogen gas at 100 pounds per square inch to project the liquid from the extinguishers, and $2^1/_2$-gallon foam extinguishers located near turbine control-oil storage tanks and around the fuel-pump area.

The lubricating-oil and control-oil tanks for the main turbines and house turbines are protected by a fixed carbon-dioxide system, consisting of piping CO_2 gas tanks, and rate-of-rise thermostats. The thermostats are mounted within the tanks near the top; when their contacts close, CO_2 gas is discharged into the oil tanks in sufficient quantity to maintain a concentration of gas of not less than 25 per cent for 30 minutes.

The main generators are hydrogen-cooled; therefore, no fire protection is required. The house generators are air-cooled and are protected by a fixed system of carbon-dioxide gas consisting of piping, nozzles, CO_2 tanks, a timing device to discharge the gas at regular intervals to maintain a 25 per cent concentration of gas within the generator casings for a time period of not less than 30 minutes. Rate-of-rise thermostats installed within the

Figure 13 (below). Boiler feed-pump motor control board

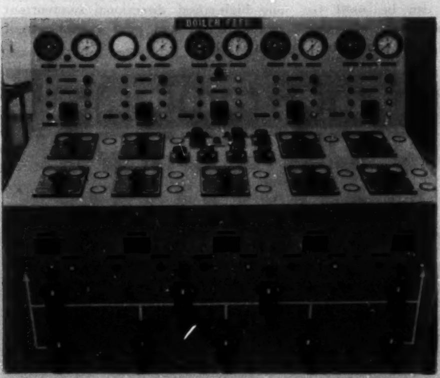

Figure 14 (right). Boiler number 6 control board

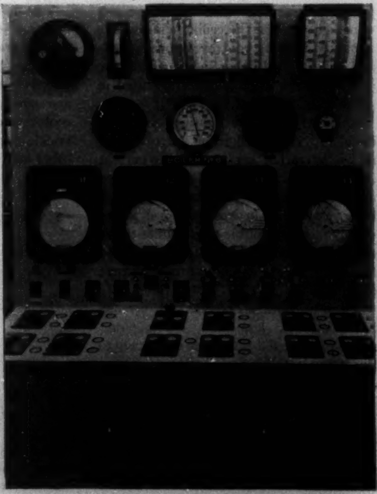

generator casing close the'r contacts when excessive temperature occurs.

A fixed mechanical foam system protects the fuel-oil tanks. The foam is projected on top of the floating roof of each tank through pipes and nozzles installed for that purpose. Additional foam nozzles will project foam around the outside of the tanks within the area surrounded by the levee. The fuel-oil pumps installed under the boilers also are protected by mechanical foam projected from hose lines which are located in that area.

A hydrant and hose system is installed both indoors and outdoors to provide general water-fog fire protection for all installations, including the 115-kv switchyard, 12-kv switchyard, main transformers, and indoor equipment. Each hydrant is equipped with 100 feet of $1^1/_2$-inch rubber-lined cotton-jacketed hose having a fixed-fog nozzle connected thereto. Water pressure at 100 pounds per square inch is maintained by two 1,000-gallon-per-minute pumps, one pump motor-driven and the other steam-turbine driven. The motor-driven pump is started by push button, from the control room.

The warehouse is protected by an automatic sprinkler system, and a flow device mounted in the main water-pipe connection to the warehouse closes an alarm contact if water flows and also starts the fire pump to increase the water pressure.

Central Control Area

The general design of this station is such that it is built around a central control area. The boilers, turbines, boiler feed pumps, fuel pumps, 110-kv feeders, and auxiliary power busses are all controlled from this area. See Figure 5. The central control area is not completely soundproofed but is open to both the boiler firing aisle and the turbine bay, as the operators become sensitive to changes of pitch or intensity of normal generating plant noise and often become aware something is amiss and requires attention before the instruments and gauges give a substantial change in indication. A large glass-enclosed telephone room is placed at the center of the control area near the vitally important switchboards, so that the operator can read the instruments and telephone the information to necessary offices. Vital control boards, such as the master panel (which controls all the boilers), main generator panels, house-generator and house-bank panels, and boiler feed-water control panels are arranged around three sides of an open square with the telephone room in the center. This is a planned arrangement to provide operators with a direct view of the important equipment, boilers, turbines, and boiler feed pumps as well as the control panels; it also provides quick access to the equipment when supervising the automatic functions of the plant. The control panels themselves are designed so that operation of each part of the equipment is logical and is oriented correctly with respect to its actual location about the plant. Instruments, gauges, control handles, and lights are deliberately arranged in unsymmetrical patterns to allow quick visual identification by the operating staff. The arrangement of the master panel is such that the boilers, circulating water pumps, and condensate pumps are controlled here.

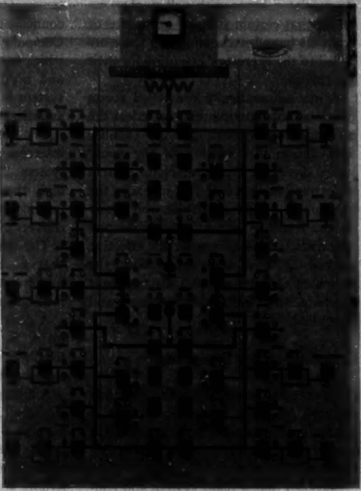

Figure 15. 4,160-volt remote control board

A generating plant using a central control scheme requires the installation of automatic control equipment such as combustion control, boiler feed-water control, fuel control, and automatic transfer equipment for circulating water pumps, condensate pumps, and many others.

Motor-driven pumps also are arranged for automatic transfer to standby pumps fed from other sources in case of loss of power, motor failure, too high or too low a pressure, too high or too low a liquid level, or excessive temperature. Such transfer operations occur automatically when the initiating contacts close, without requiring attention or supervision from the station operators.

Annunciators and Alarm Circuits

A centrally controlled plant requires an extensive alarm system, as the many automatic devices must report their operation to the central control area. Therefore a complete annunciator and alarm system is installed, giving both audible and visual indication. The annunciator boxes are large, giving good visibility from a distance of 30 to 40 feet; their electric circuits are designed so that the audible alarm (horn or bell) may be shut off while the annunciator box remains lighted; the horn or bell are then available to announce other operations. This plant has many transfer devices which also require annunciator boxes whose function is to indicate that a transfer has been initiated and has been completed swiftly and accurately. The operation of some devices requires immediate attention, while others indicate a routine operation; therefore, some annunciator boxes are equipped with colored glass to call attention to the degree of urgency of the alarm. An annunciator box with red glass indicates that immediate attention must be given to the device initiating this alarm. Annunicator boxes with white glass indicate an operation of lesser importance than those indicated by red glass, and attention may be deferred until the general emergency period is over.

Annunciator boxes with yellow glass indicate that certain standby operations or transfers have been completed; these are called to the operators' attention for their information.

A semiautomatically controlled steam plant cannot function reliably unless the personnel understand and are familiar with abnormal operation of the many varied devices. The annunciator system is designed so that each box indicates the function of a separate device which may be the result of a routine or abnormal operation. This serves as an effective method of continually reminding the personnel of the many and diverse plant functions that must be supervised and controlled.

Communication Equipment

An extensive communicating system is required for large steam plants. It is used in conjunction with the annunciator system for plant maintenance and operation.

Station P has a plant system and connections to two outside telephone systems. One installation of telephones is connected to the Pacific Gas and Electric Company's private telephone system, which has a network covering the central and northern part of California. This system is used for both routine business and dispatching requirements.

The company's private system also is interconnected with the plant interphone system. The latter system is automatic, dial type, selective ringing, selective talking, and capable of handling five conversations simultaneously.

The other outside telephone system is that of the local telephone company; four trunks have been installed to handle routine business in San Francisco.

A code call system is installed in the plant, in conjunction with the private telephone system, for calling station personnel to the nearest telephone.

A 2-wire telephone circuit has been installed within the station for maintenance purposes. Many polarized 2-wire outlets have been installed throughout the plant, from the top of the boilers to the remote areas on the first floor of the turbine room. Maintenance personnel plug their telephone hand sets into convenient outlets and thus have a common communication circuit for their use.

Conclusion

The electrical control of this plant is arranged to co-ordinate the general plant design of automatic control of major steam generating and fuel equipment and automatic transfer of many other motor-driven devices. This requires personnel who are adequately trained and resourceful, as they must correctly interpret the function of a device initiating an alarm in relation to other devices about the plant. The central control area design necessitates use of the many advantages of automatic control for equipment functions, and the use of an extensive annunciator system to acquaint the operators and keep them informed of the normal equipment functions, as well as calling attention to abnormal or faulty operation.

The electric installation was designed and installed by the Stone and Webster Engineering Company for the Pacific Gas and Electric Company.

Discussion

V. F. Estcourt (Pacific Gas and Electric Company, San Francisco, Calif.): The author is to be congratulated for having prepared a very comprehensive description of the electrical design features of the Pacific Gas and Electric Company's Station P. I have been asked to comment on this paper with particular reference to some of the automatic control features, and the centralization of a great many of these controls in one control room.

Before discussing the Station P control layout in more detail, it is essential to understand the fundamental operating objectives underlying this type of design. Due to the fact that the Pacific Gas and Electric Company's generating facilities are divided about equally between steam and hydro, seasonal variations in rainfall and water storage make it necessary to operate the steam plants over very wide load ranges, that is, from approximately 10 to 100% of their rated capacity. They also must be prepared to pick up large blocks of load in a matter of seconds in the event of any interruption to the incoming power generated from hydroelectric sources and delivered over long-distance transmission lines.

The first major experience of the Pacific Gas and Electric Company with the application of full automatic decentralized control for steam plant operation dates back to the year 1934 in connection with the 120,000-kw 1,400-pound, 750 degree Fahrenheit—750 degree Fahrenheit reheat Station A in San Francisco. As a result of several years of development and experimental work, this plant operated successfully on full automatic control under operating conditions ranging from base load to wide load range operation at rates of load change in excess of 1,500 kw per second with either natural gas or fuel oil firing. The first plant with a large amount of centralized control was installed in 1940 and subsequent installations such as Station P have followed the same general pattern.

Automatic control, as applied to steam plant operation, is intended to accomplish the following basic objectives:

1. The establishment of uniform operating patterns by incorporating these into the control devices, so that not only is maximum operating efficiency and reliability obtained, but individual operators are prevented from introducing variations from the optimum pattern which has been determined by careful tests.

2. Reduction of psychological stress upon the operator to a minimum so that his mind is free to concentrate upon the overall picture, with particular reference to trouble conditions, rather than have his attention diverted by the need for handling manually numerous operating adjustments and load changes.

3. The final objective is to combine the aforementioned advantages of automatic control into a layout which will permit the centralization of a large proportion of these controls, instruments, and alarm signals in one main control room. By means of carefully planned centralization, the advantages of full automatic control are all the more accentuated and the net result is more reliable operation, less operating errors, and a smaller operating crew, with resultant lower operating costs. In fact, with a decentralized control job, it is doubtful whether as much automatic control can be justified for the reason that more operators are required and their respective duties and responsibilities are correspondingly less. However, the problem of communication and general co-ordination of operating activities is thereby greatly aggravated, particularly during trouble conditions.

As has been pointed out by the author, the major equipment at Station P, which includes the boilers, turbines, and boiler feed pumps, is grouped around the control room; the firing aisle, control room, and turbine deck are at the same elevation, thereby providing the operators in the control room with direct vision of and close access to these major components of the plant.

This has the effect of keeping the operators inherently centralized in one location with a relatively short-radius area to patrol for the purpose of inspecting and handling such equipment. Much of the advantage of a centralized control room will be lost if consideration is not given to the orientation of major equipment with respect to this central control room, for the reason that it will require additional operators stationed around the important items of equipment due to their inaccessibility from the control room. If it is necessary to keep a number of operators in decentralized locations, then it is difficult to justify a highly centralized control layout.

The author has referred to the automatic starting of standby pumps. This has to do particularly with various items of auxiliary equipment located at plant elevations other than the control room, and which are therefore inaccessible to the control operators in the control room. Two or three shift operators are all that are required to patrol and inspect these minor auxiliaries which are located on the lower floor of the turbine room and boiler room and in the yard outside the main building. This would not be possible without a very reliable system for the automatic starting of standby equipment plus an adequate alarm system to warn the operators in the control room as to certain types of operating trouble. Our practice is to use two initiating sources for automatically starting any piece of standby equipment. These sources are usually undervoltage at the motor terminals plus pump discharge pressure or tank level as the case may be.

Bringing most of the controls into a central control room, plus other necessary related features, probably has added approximately 50 per cent to the total investment cost of such a control layout as compared with a completely decentralized job. This additional investment cost is more than offset by the saving in shift operating labor and greater operating reliability. Furthermore, as a result of our operating experience at the Kern Steam Plant and also at Station P, it is believed that we can make an appreciable reduction in the cost of controls in our future installations by eliminating from the control room certain controls and control panels which are in effect a duplication of local controls elsewhere in the plant. We were afraid to do this at either Kern or Station P, due to lack of sufficient experience with the operation of some of these controls under severe operating conditions. Therefore, we were quite generous with respect to the amount of remote controls which were brought into the control room. However, the actual performance of the various automatic features has come up to our most optimistic expectations, and we now are satisfied that some of these remove controls located in the main control room can be eliminated without impairing operating reliability. It is therefore anticipated that the advantages that have been realized through centralized control can be accomplished in the future at a substantially lower investment cost.

There are three control operators stationed on the main operating floor, and they are headquartered in the control room. Due to the fact that the operator has a full view of the firing aisle from the control room and also, due to the visibility and close proximity of the boiler feed pumps and main turbines to the control room, these same three operators are able to take care of patrolling this major equipment. These control operators are trained to handle both the electrical and mechanical equipment. Some of them were originally electrical operators but probably about two-thirds of them were only mechanically trained.

The nucleus of the shift operating organization at Station P was transferred from other centralized control plants where these men had already received a combination electrical and mechanical training. The balance of the organization has been built around this nucleus. Our present practice, in the case of a fairly large job such as Station P, is to assign two full-time instructors for a period of months for the purpose of training the shift operating organization. One of these instructors devotes his entire time to electrical instruction and the other to mechanical instruction; and of course, the operating background of these two instructors makes them particularly qualified to handle their respective assignments, and it also is necessary that they work with each other in order to properly co-ordinate this program instruction.

W. Ridgway (General Electric Company, San Francisco, Calif.): It is immediately evident upon reading this paper that many aspects of this plant show the most modern engineering practices. I should like to elaborate on several features of particular interest.

The unit type main generator excitation system with its high inertia motor driven exciter set provides the most reliable and effective equipment available. The exciter set is designed to meet or exceed the performance characteristics of a direct-connected exciter with maintenance advantages of a separate motor-generator set operating at lower speed.

An amplidyne generator is direct-connected to the shaft of the exciter set and is controlled by a static circuit to provide regulation of the main generator armature voltage. A feature of this static circuit is a lower limit of excitation which is automatically varied proportional to the generator kilowatt loading. This permits under-excited operation of the turbine generator with a reasonable margin of excitation over the steady-state pull-out point for any given loading condition. Local system conditions indicate that this may be a particularly valuable operating tool at this station.

The metal-enclosed isolated phase bus runs and station-type air blast circuit breakers afford fully co-ordinated interconnections between the generator terminals and the house and main transformer banks. Each phase of the bus runs is enclosed in a square aluminum duct. It is dust-tight and watertight and provides complete protection from phase-to-phase faults. Each continuous length of duct is completely sealed and all circulating current paths are broken by insulating joints. Each length is provided with a hinged door for ready access to the interior for inspection.

The station-type air blast circuit breakers are completely metal enclosed and are furnished with a main and stand-by air compressor. Phase isolation is maintained throughout the equipment. Internal illumination of the disconnect switch compartments has been provided for the convenience of the operator. All current transformers are provided with terminal blocks located in a metal-enclosed compartment which is accessible without opening any live compartment. The circuit breaker mechanism is designed for 5-cycle interruption and is provided with complete interlocking for safety of the equipment and operating personnel. Use of 250 pound-per-square-inch air for circuit breaker operation permits smaller air receivers for a given volume of air and results in improved arc interruption.

The hydrogen-cooled turbine generators are rated at 15 pound-per-square-inch hydrogen pressure. Suitable gas seals have been provided for 25 pound-per-square-inch operation should the additional generator capacity available at the higher pressure be desired.

In his discussion, Mr. Whelchel has thoroughly covered the place of house turbines in modern steam plant design. Suffice to say here that in some of the newest plants the house generators and house transformer banks between the generator terminals and the auxiliary station power bus have been omitted entirely. Thus no switching is necessary at generator voltage and the main transformer bank is fed direct from the generator terminals. Power for station auxiliaries is obtained from a transformer bank connected to the high-voltage system.

This simplified construction has permitted considerable economies in steam plant initial investment and may be employed where the integrity of the high-voltage system is unquestioned. As more plants similar to Station P are completed, this integrity should be realized on the Pacific Gas and Electric system.

C. C. Whelchel (Pacific Gas and Electric Company, San Francisco, Calif.): Mr. Benson's paper includes a description of the auxiliary station power supply made up of house turbinegenerators and house transformer banks. Since house turbinegenerators have found their widest application on the West Coast, some additional comments on why they are required, may be of interest.

Primarily the function of the house turbinegenerator is to supply independent 60-cycle full-voltage power to the station auxiliary motors during system disturbances. Their need is therefore dictated by the electrical design and operation of the system.

The Pacific Gas and Electric Company, like some others on the West Coast, has large blocks of hydro-electric generating capacity located at considerable distances from the load. Initially, and to some extent now, this power was brought in over long distance high-voltage lines with an electrical system design which essentially amounted to "synchronizing at the load" with the reliability of generation tied up with its associated transmission line. This form of system design could be and perhaps was carried further in the relatively lightning-free California territory than elsewhere. Although having lower first cost, it was necessary with such a design to take other steps to protect service—one of these being "quick pick-up" main steam generating units with their house turbinegenerators located near the system electrical load center.

The greatest usefulness of house turbinegenerators occurs when the main steam units are operating at light load and due to the loss of a large block of generating capacity elsewhere, it is desired to load the steam units in the shortest possible time. During such disturbances the system voltage and frequency will have fallen to such an extent that the auxiliaries in the steam plant must be transferred to the house unit in order to continue to operate satisfactorily. By this transfer of plant auxiliaries the main unit is in a position to pick up from light load to more than 3/4 load in 30 seconds or less, regardless of low-system voltage and frequency. To the degree that house units contribute to the economical solution of the system electrical problem which has been described, then to that degree it is believed that they are justified.

We recognize that there are power systems in this country that upon the sudden loss of generation automatically reduce load to maintain system frequency at a predetermined minimum on the assumption that the least over-all disturbance occurs when load and generating capacity are approximately matched.

The success of this method of operation plus splitting up the system electrically in case of trouble depends on the characteristics of the particular system under consideration. As conditions permit, this approach to the problem is receiving attention by the Pacific Gas and Electric Company. The objective on any power system is to design the steam stations as simply as possible to meet system requirements. As integration and growth continues, the need for additional "quick pick-up" steam stations with their house turbinegenerators will probably tend to decline. The future trend of steam station design here as well as elsewhere is expected to be in the direction of simplification of equipment and plant layout and still lower station heat rates.

Matching Electrical Characteristics of McNary Generators and Transformers with Bonneville Power Administration Transmission System

B. V. HOARD
MEMBER AIEE

LEWIS WEINER
ASSOCIATE AIEE

CARRYING out the planned orderly development of the Columbia River for power, navigation, reclamation, and flood control purposes, the Federal Government has selected the McNary damsite as the next major project. The site is located on the main stem of the lower Columbia River between the present Bonneville and Grand Coulee dams and near Umatilla, Oreg. The dam will produce slack water approximately 59 miles up the river to a point approximately 32 miles above the mouth of the Snake River. The ultimate installed capacity of the power plant will consist of 14 generating units rated at 73,684 kva each at 95 per cent power factor, thereby permitting the plant to generate 1,127,000 kw at rated power factor, including an overload of 15 per cent which the generating units are being designed to handle. Present plans call for the installation of 10 to 12 of these units with the balance of the machines to await the development of other up-stream plants which will provide sufficient increased storage reservoir capacity to justify installation of the additional units.

The McNary project, being constructed on a navigable stream with important navigation as well as power features, will be under the authority of the Corps of Engineers, United States Army, and hence will be designed, constructed, and operated by that agency. The Bonneville Power Administration (BPA) has the responsibility of transmitting and marketing the power and providing payout of costs of the transmission system and those costs of the generating station chargeable to power purposes for all Federal multipurpose projects within the Columbia River Basin. Hence, the Administration will receive the power generated at McNary and will provide the transmission network necessary to deliver this power to the distant load centers. It is vitally interested in the cost features of the dam and generating plant properly chargeable to power.

The engineers of both Federal agencies recognized that the electrical characteristics which are built into the generating and transformer equipment at McNary would have a great effect upon the overall economy and the operating characteristics of the complete system, and that close co-operation between the two agencies would obtain a combination of generating plant and transmission system which would adequately serve the needs of the area and obtain the least total cost to the Federal Government. Accordingly, the agencies have worked closely together to this end. The Corps of Engineers requested the BPA to study and recommend the characteristics for the generators and transformers to be installed at McNary. This request resulted in the following:

1. The generators should have a transient reactance not greater than 32 per cent on the generator rating of 73,684 kva at 95 per cent power factor.

2. Continuous damper windings should be provided that will give a ratio of X_q''/X_d'' not greater than 1.1, as determined by tests at air-gap excitation corresponding to rated current, power factor, and voltage with X_q'' determined from X_2.

3. The exciter response should be not less than 1.5.

4. The transformers should have a reactance of not more than 8 per cent on the bank rating of 169,500 kva with two generators connected to a bank.

Following these recommendations, cost figures were compiled by the Corps of Engineers which indicated that the transient reactance for minimum-cost machines for the McNary installation would be 44 per cent on a base of 73,684 kva. With an additional installed cost of $1,550,000 for 14 machines, it would be possible to obtain machines having the recommended transient reactances of 32 per cent. Similarly, reactances for minimum cost transformers, each bank of which is designed to carry the output of two generators, would be 13.5 per cent on a base of 169,500 kva, but this value could be reduced to as low as 8 per cent with an additional cost of $590,000 for seven such banks of transformers. Other additional costs would be incurred with low-reactance units because of the greater physical size of such equipment. These costs included greater investment in the powerhouse and crane and an equivalent capitalized value due to lowered generator efficiency. The total increased cost for reduced reactances for both machines and transformers was calculated to be $3,200,000 including all these factors as compared with the cost of minimum-cost equipment. Obviously, a strong justification was needed for the expenditure of $3,200,000 for special characteristics for the McNary generators and transformers; therefore the Corps of Engineers requested the BPA to prepare this justification.

Paper 49-209, recommended by the AIEE Transmission and Distribution Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Pacific General Meeting, San Francisco, Calif., August 23-26, 1949. Manuscript submitted May 13, 1949; made available for printing June 29, 1949.

B. V. Hoard and Lewis Weiner are both with the Bonneville Power Administration, Portland, Oreg. The authors wish to express their appreciation to R. C. Schuknecht, L. K. Fisher, and E. C. Starr for their assistance in the preparation of this paper.

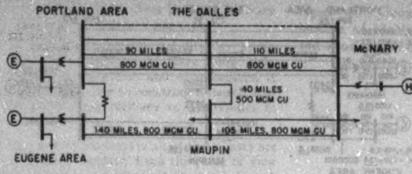

Figure 1. Transmission system for McNary generation

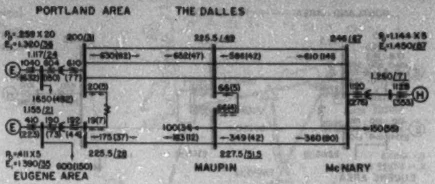

Figure 1(A). Load flow diagram 1

McNary reactances $X_d'=32$ per cent on 73.68-megavolt-ampere base; X of transformer = 8 per cent on 170-megavolt-ampere base; 1,128-megawatt output at McNary; maximum swing—104.5 degrees

System Studied

The most satisfactory measure of the benefits to be gained from lower reactance facilities at McNary is a comparison of the maximum power which can be transmitted over the power system with high- and low-reactance terminal equipment, and a determination of what additional transmission facilities must be installed with high-reactance equipment to obtain the same stability as with low-reactance equipment. These factors were obtained through use of the Administration's a-c network analyzer.
